

# scikit-learn user guide

*Release 0.19.dev0*

scikit-learn developers

Jun 08, 2017

# CONTENTS

<b>1</b>	<b>Welcome to scikit-learn</b>	<b>1</b>
1.1	Installing scikit-learn . . . . .	1
1.2	Frequently Asked Questions . . . . .	2
1.3	Support . . . . .	7
1.4	Related Projects . . . . .	8
1.5	About us . . . . .	11
1.6	Who is using scikit-learn? . . . . .	15
1.7	Release history . . . . .	23
<b>2</b>	<b>scikit-learn Tutorials</b>	<b>97</b>
2.1	An introduction to machine learning with scikit-learn . . . . .	97
2.2	A tutorial on statistical-learning for scientific data processing . . . . .	103
2.3	Working With Text Data . . . . .	128
2.4	Choosing the right estimator . . . . .	135
2.5	External Resources, Videos and Talks . . . . .	135
<b>3</b>	<b>User Guide</b>	<b>139</b>
3.1	Supervised learning . . . . .	139
3.2	Unsupervised learning . . . . .	276
3.3	Model selection and evaluation . . . . .	365
3.4	Dataset transformations . . . . .	492
3.5	Dataset loading utilities . . . . .	528
3.6	Strategies to scale computationally: bigger data . . . . .	555
3.7	Computational Performance . . . . .	558
<b>4</b>	<b>General examples</b>	<b>569</b>
4.1	Plotting Cross-Validated Predictions . . . . .	569
4.2	Isotonic Regression . . . . .	570
4.3	Concatenating multiple feature extraction methods . . . . .	572
4.4	Pipelining: chaining a PCA and a logistic regression . . . . .	576
4.5	Imputing missing values before building an estimator . . . . .	577
4.6	Face completion with a multi-output estimators . . . . .	579
4.7	Selecting dimensionality reduction with Pipeline and GridSearchCV . . . . .	581
4.8	Multilabel classification . . . . .	592
4.9	The Johnson-Lindenstrauss bound for embedding with random projections . . . . .	595
4.10	Comparison of kernel ridge regression and SVR . . . . .	601
4.11	Feature Union with Heterogeneous Data Sources . . . . .	605
4.12	Explicit feature map approximation for RBF kernels . . . . .	608
<b>5</b>	<b>Examples based on real world datasets</b>	<b>613</b>

5.1	Outlier detection on a real data set . . . . .	613
5.2	Compressive sensing: tomography reconstruction with L1 prior (Lasso) . . . . .	616
5.3	Faces recognition example using eigenfaces and SVMs . . . . .	619
5.4	Topic extraction with Non-negative Matrix Factorization and Latent Dirichlet Allocation . . . . .	623
5.5	Model Complexity Influence . . . . .	627
5.6	Species distribution modeling . . . . .	633
5.7	Visualizing the stock market structure . . . . .	637
5.8	Wikipedia principal eigenvector . . . . .	643
5.9	Libsvm GUI . . . . .	647
5.10	Prediction Latency . . . . .	652
5.11	Out-of-core classification of text documents . . . . .	660
<b>6</b>	<b>Biclustering</b>	<b>671</b>
6.1	A demo of the Spectral Co-Clustering algorithm . . . . .	671
6.2	A demo of the Spectral Biclustering algorithm . . . . .	673
6.3	Biclustering documents with the Spectral Co-clustering algorithm . . . . .	675
<b>7</b>	<b>Calibration</b>	<b>679</b>
7.1	Comparison of Calibration of Classifiers . . . . .	679
7.2	Probability Calibration curves . . . . .	682
7.3	Probability calibration of classifiers . . . . .	687
7.4	Probability Calibration for 3-class classification . . . . .	689
<b>8</b>	<b>Classification</b>	<b>695</b>
8.1	Recognizing hand-written digits . . . . .	695
8.2	Normal and Shrinkage Linear Discriminant Analysis for classification . . . . .	697
8.3	Plot classification probability . . . . .	699
8.4	Classifier comparison . . . . .	702
8.5	Linear and Quadratic Discriminant Analysis with covariance ellipsoid . . . . .	705
<b>9</b>	<b>Clustering</b>	<b>709</b>
9.1	A demo of the mean-shift clustering algorithm . . . . .	709
9.2	A demo of structured Ward hierarchical clustering on a raccoon face image . . . . .	711
9.3	Feature agglomeration . . . . .	713
9.4	Demonstration of k-means assumptions . . . . .	714
9.5	Online learning of a dictionary of parts of faces . . . . .	716
9.6	Demo of affinity propagation clustering algorithm . . . . .	719
9.7	Segmenting the picture of a raccoon face in regions . . . . .	721
9.8	Hierarchical clustering: structured vs unstructured ward . . . . .	723
9.9	Vector Quantization Example . . . . .	726
9.10	Agglomerative clustering with and without structure . . . . .	728
9.11	Demo of DBSCAN clustering algorithm . . . . .	731
9.12	K-means Clustering . . . . .	733
9.13	Spectral clustering for image segmentation . . . . .	735
9.14	Various Agglomerative Clustering on a 2D embedding of digits . . . . .	738
9.15	Color Quantization using K-Means . . . . .	741
9.16	Agglomerative clustering with different metrics . . . . .	744
9.17	Comparison of the K-Means and MiniBatchKMeans clustering algorithms . . . . .	748
9.18	Feature agglomeration vs. univariate selection . . . . .	750
9.19	Compare BIRCH and MiniBatchKMeans . . . . .	753
9.20	Empirical evaluation of the impact of k-means initialization . . . . .	756
9.21	Adjustment for chance in clustering performance evaluation . . . . .	759
9.22	A demo of K-Means clustering on the handwritten digits data . . . . .	762
9.23	Selecting the number of clusters with silhouette analysis on KMeans clustering . . . . .	765
9.24	Comparing different clustering algorithms on toy datasets . . . . .	769

<b>10 Covariance estimation</b>	<b>773</b>
10.1 Ledoit-Wolf vs OAS estimation . . . . .	773
10.2 Sparse inverse covariance estimation . . . . .	775
10.3 Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood . . . . .	778
10.4 Robust covariance estimation and Mahalanobis distances relevance . . . . .	781
10.5 Outlier detection with several methods. . . . .	784
10.6 Robust vs Empirical covariance estimate . . . . .	788
<b>11 Cross decomposition</b>	<b>793</b>
11.1 Compare cross decomposition methods . . . . .	793
<b>12 Dataset examples</b>	<b>799</b>
12.1 The Digit Dataset . . . . .	799
12.2 The Iris Dataset . . . . .	800
12.3 Plot randomly generated classification dataset . . . . .	802
12.4 Plot randomly generated multilabel dataset . . . . .	804
<b>13 Decomposition</b>	<b>807</b>
13.1 Beta-divergence loss functions . . . . .	807
13.2 PCA example with Iris Data-set . . . . .	808
13.3 Incremental PCA . . . . .	809
13.4 Comparison of LDA and PCA 2D projection of Iris dataset . . . . .	811
13.5 Blind source separation using FastICA . . . . .	813
13.6 FastICA on 2D point clouds . . . . .	815
13.7 Kernel PCA . . . . .	818
13.8 Principal components analysis (PCA) . . . . .	819
13.9 Model selection with Probabilistic PCA and Factor Analysis (FA) . . . . .	822
13.10 Sparse coding with a precomputed dictionary . . . . .	824
13.11 Faces dataset decompositions . . . . .	827
13.12 Image denoising using dictionary learning . . . . .	832
<b>14 Ensemble methods</b>	<b>839</b>
14.1 Decision Tree Regression with AdaBoost . . . . .	839
14.2 Pixel importances with a parallel forest of trees . . . . .	840
14.3 IsolationForest example . . . . .	842
14.4 Feature importances with forests of trees . . . . .	844
14.5 Plot the decision boundaries of a VotingClassifier . . . . .	846
14.6 Comparing random forests and the multi-output meta estimator . . . . .	848
14.7 Gradient Boosting regression . . . . .	850
14.8 Prediction Intervals for Gradient Boosting Regression . . . . .	853
14.9 Plot class probabilities calculated by the VotingClassifier . . . . .	855
14.10 Gradient Boosting regularization . . . . .	857
14.11 OOB Errors for Random Forests . . . . .	859
14.12 Two-class AdaBoost . . . . .	861
14.13 Hashing feature transformation using Totally Random Trees . . . . .	864
14.14 Partial Dependence Plots . . . . .	866
14.15 Discrete versus Real AdaBoost . . . . .	869
14.16 Multi-class AdaBoosted Decision Trees . . . . .	871
14.17 Feature transformations with ensembles of trees . . . . .	874
14.18 Gradient Boosting Out-of-Bag estimates . . . . .	876
14.19 Single estimator versus bagging: bias-variance decomposition . . . . .	879
14.20 Plot the decision surfaces of ensembles of trees on the iris dataset . . . . .	884
<b>15 Tutorial exercises</b>	<b>889</b>
15.1 Digits Classification Exercise . . . . .	889

15.2	Cross-validation on Digits Dataset Exercise . . . . .	890
15.3	SVM Exercise . . . . .	891
15.4	Cross-validation on diabetes Dataset Exercise . . . . .	893
<b>16</b>	<b>Feature Selection</b>	<b>897</b>
16.1	Recursive feature elimination . . . . .	897
16.2	Comparison of F-test and mutual information . . . . .	898
16.3	Pipeline Anova SVM . . . . .	899
16.4	Recursive feature elimination with cross-validation . . . . .	900
16.5	Feature selection using SelectFromModel and LassoCV . . . . .	902
16.6	Univariate Feature Selection . . . . .	903
16.7	Test with permutations the significance of a classification score . . . . .	907
<b>17</b>	<b>Gaussian Process for Machine Learning</b>	<b>911</b>
17.1	Illustration of Gaussian process classification (GPC) on the XOR dataset . . . . .	911
17.2	Gaussian process classification (GPC) on iris dataset . . . . .	912
17.3	Comparison of kernel ridge and Gaussian process regression . . . . .	914
17.4	Gaussian process regression (GPR) on Mauna Loa CO <sub>2</sub> data. . . . .	917
17.5	Illustration of prior and posterior Gaussian process for different kernels . . . . .	920
17.6	Iso-probability lines for Gaussian Processes classification (GPC) . . . . .	924
17.7	Probabilistic predictions with Gaussian process classification (GPC) . . . . .	926
17.8	Gaussian process regression (GPR) with noise-level estimation . . . . .	929
17.9	Gaussian Processes regression: basic introductory example . . . . .	931
<b>18</b>	<b>Generalized Linear Models</b>	<b>935</b>
18.1	Lasso path using LARS . . . . .	935
18.2	Plot Ridge coefficients as a function of the regularization . . . . .	936
18.3	Path with L1- Logistic Regression . . . . .	938
18.4	SGD: Maximum margin separating hyperplane . . . . .	940
18.5	SGD: convex loss functions . . . . .	942
18.6	Plot Ridge coefficients as a function of the L2 regularization . . . . .	943
18.7	Ordinary Least Squares and Ridge Regression Variance . . . . .	945
18.8	Logistic function . . . . .	946
18.9	Polynomial interpolation . . . . .	948
18.10	Logistic Regression 3-class Classifier . . . . .	950
18.11	SGD: Weighted samples . . . . .	952
18.12	Linear Regression Example . . . . .	953
18.13	Lasso on dense and sparse data . . . . .	955
18.14	Lasso and Elastic Net for Sparse Signals . . . . .	957
18.15	Sparsity Example: Fitting only features 1 and 2 . . . . .	959
18.16	Robust linear model estimation using RANSAC . . . . .	961
18.17	Joint feature selection with multi-task Lasso . . . . .	963
18.18	Comparing various online solvers . . . . .	965
18.19	HuberRegressor vs Ridge on dataset with strong outliers . . . . .	967
18.20	SGD: Penalties . . . . .	969
18.21	MNIST classification using multinomial logistic + L1 . . . . .	971
18.22	Orthogonal Matching Pursuit . . . . .	973
18.23	Plot multi-class SGD on the iris dataset . . . . .	978
18.24	Theil-Sen Regression . . . . .	981
18.25	L1 Penalty and Sparsity in Logistic Regression . . . . .	983
18.26	Plot multinomial and One-vs-Rest Logistic Regression . . . . .	986
18.27	Robust linear estimator fitting . . . . .	988
18.28	Bayesian Ridge Regression . . . . .	991
18.29	Automatic Relevance Determination Regression (ARD) . . . . .	994

18.30 Lasso and Elastic Net . . . . .	997
18.31 Lasso model selection: Cross-Validation / AIC / BIC . . . . .	1000
18.32 Multiclass sparse logistic regression on newsgroups20 . . . . .	1004
18.33 Sparse recovery: feature selection for sparse linear models . . . . .	1008
<b>19 Manifold learning</b>	<b>1013</b>
19.1 Swiss Roll reduction with LLE . . . . .	1013
19.2 Multi-dimensional scaling . . . . .	1014
19.3 Comparison of Manifold Learning methods . . . . .	1017
19.4 Manifold Learning methods on a severed sphere . . . . .	1019
19.5 Manifold learning on handwritten digits: Locally Linear Embedding, Isomap... . . . . .	1023
<b>20 Gaussian Mixture Models</b>	<b>1033</b>
20.1 Density Estimation for a Gaussian mixture . . . . .	1033
20.2 Gaussian Mixture Model Ellipsoids . . . . .	1034
20.3 Gaussian Mixture Model Selection . . . . .	1036
20.4 GMM covariances . . . . .	1039
20.5 Gaussian Mixture Model Sine Curve . . . . .	1042
20.6 Concentration Prior Type Analysis of Variation Bayesian Gaussian Mixture . . . . .	1046
<b>21 Model Selection</b>	<b>1051</b>
21.1 Plotting Validation Curves . . . . .	1051
21.2 Underfitting vs. Overfitting . . . . .	1052
21.3 Train error vs Test error . . . . .	1054
21.4 Receiver Operating Characteristic (ROC) with cross validation . . . . .	1056
21.5 Parameter estimation using grid search with cross-validation . . . . .	1059
21.6 Confusion matrix . . . . .	1062
21.7 Comparing randomized search and grid search for hyperparameter estimation . . . . .	1064
21.8 Nested versus non-nested cross-validation . . . . .	1066
21.9 Sample pipeline for text feature extraction and evaluation . . . . .	1069
21.10 Receiver Operating Characteristic (ROC) . . . . .	1071
21.11 Precision-Recall . . . . .	1075
21.12 Plotting Learning Curves . . . . .	1079
<b>22 Nearest Neighbors</b>	<b>1083</b>
22.1 Nearest Neighbors regression . . . . .	1083
22.2 Anomaly detection with Local Outlier Factor (LOF) . . . . .	1084
22.3 Nearest Neighbors Classification . . . . .	1086
22.4 Nearest Centroid Classification . . . . .	1088
22.5 Kernel Density Estimation . . . . .	1089
22.6 Kernel Density Estimate of Species Distributions . . . . .	1091
22.7 Simple 1D Kernel Density Estimation . . . . .	1094
22.8 Hyper-parameters of Approximate Nearest Neighbors . . . . .	1098
22.9 Scalability of Approximate Nearest Neighbors . . . . .	1100
<b>23 Neural Networks</b>	<b>1105</b>
23.1 Visualization of MLP weights on MNIST . . . . .	1105
23.2 Restricted Boltzmann Machine features for digit classification . . . . .	1107
23.3 Compare Stochastic learning strategies for MLPClassifier . . . . .	1111
23.4 Varying regularization in Multi-layer Perceptron . . . . .	1115
<b>24 Preprocessing</b>	<b>1119</b>
24.1 Using FunctionTransformer to select columns . . . . .	1119
24.2 Robust Scaling on Toy Data . . . . .	1121
24.3 Importance of Feature Scaling . . . . .	1123

<b>25 Semi Supervised Classification</b>	<b>1127</b>
25.1 Label Propagation learning a complex structure . . . . .	1127
25.2 Label Propagation digits: Demonstrating performance . . . . .	1128
25.3 Decision boundary of label propagation versus SVM on the Iris dataset . . . . .	1131
25.4 Label Propagation digits active learning . . . . .	1133
<b>26 Support Vector Machines</b>	<b>1139</b>
26.1 Support Vector Regression (SVR) using linear and non-linear kernels . . . . .	1139
26.2 Non-linear SVM . . . . .	1140
26.3 SVM: Maximum margin separating hyperplane . . . . .	1142
26.4 SVM: Separating hyperplane for unbalanced classes . . . . .	1143
26.5 SVM-Anova: SVM with univariate feature selection . . . . .	1145
26.6 SVM with custom kernel . . . . .	1147
26.7 SVM: Weighted samples . . . . .	1148
26.8 SVM-Kernels . . . . .	1150
26.9 SVM Margins Example . . . . .	1152
26.10 One-class SVM with non-linear kernel (RBF) . . . . .	1154
26.11 Plot different SVM classifiers in the iris dataset . . . . .	1156
26.12 Scaling the regularization parameter for SVCs . . . . .	1159
26.13 RBF SVM parameters . . . . .	1163
<b>27 Working with text documents</b>	<b>1167</b>
27.1 FeatureHasher and DictVectorizer Comparison . . . . .	1167
27.2 Clustering text documents using k-means . . . . .	1169
27.3 Classification of text documents using sparse features . . . . .	1173
<b>28 Decision Trees</b>	<b>1179</b>
28.1 Decision Tree Regression . . . . .	1179
28.2 Multi-output Decision Tree Regression . . . . .	1180
28.3 Plot the decision surface of a decision tree on the iris dataset . . . . .	1182
28.4 Understanding the decision tree structure . . . . .	1184
<b>29 API Reference</b>	<b>1189</b>
29.1 sklearn.base: Base classes and utility functions . . . . .	1189
29.2 sklearn.cluster: Clustering . . . . .	1193
29.3 sklearn.cluster.bicluster: Biclustering . . . . .	1230
29.4 sklearn.covariance: Covariance Estimators . . . . .	1235
29.5 sklearn.model_selection: Model Selection . . . . .	1264
29.6 sklearn.datasets: Datasets . . . . .	1314
29.7 sklearn.decomposition: Matrix Decomposition . . . . .	1361
29.8 sklearn.dummy: Dummy estimators . . . . .	1413
29.9 sklearn.ensemble: Ensemble Methods . . . . .	1418
29.10 sklearn.exceptions: Exceptions and warnings . . . . .	1448
29.11 sklearn.feature_extraction: Feature Extraction . . . . .	1452
29.12 sklearn.feature_selection: Feature Selection . . . . .	1479
29.13 sklearn.gaussian_process: Gaussian Processes . . . . .	1512
29.14 sklearn.isotonic: Isotonic regression . . . . .	1549
29.15 sklearn.kernel_approximation Kernel Approximation . . . . .	1554
29.16 sklearn.kernel_ridge Kernel Ridge Regression . . . . .	1562
29.17 sklearn.discriminant_analysis: Discriminant Analysis . . . . .	1565
29.18 sklearn.linear_model: Generalized Linear Models . . . . .	1573
29.19 sklearn.manifold: Manifold Learning . . . . .	1676
29.20 sklearn.metrics: Metrics . . . . .	1695
29.21 sklearn.mixture: Gaussian Mixture Models . . . . .	1760
29.22 sklearn.multiclass: Multiclass and multilabel classification . . . . .	1771

29.23 <code>sklearn.multioutput</code> : Multioutput regression and classification . . . . .	1780
29.24 <code>sklearn.naive_bayes</code> : Naive Bayes . . . . .	1785
29.25 <code>sklearn.neighbors</code> : Nearest Neighbors . . . . .	1795
29.26 <code>sklearn.neural_network</code> : Neural network models . . . . .	1850
29.27 <code>sklearn.calibration</code> : Probability Calibration . . . . .	1864
29.28 <code>sklearn.cross_decomposition</code> : Cross decomposition . . . . .	1867
29.29 <code>sklearn.pipeline</code> : Pipeline . . . . .	1881
29.30 <code>sklearn.preprocessing</code> : Preprocessing and Normalization . . . . .	1890
29.31 <code>sklearn.random_projection</code> : Random projection . . . . .	1926
29.32 <code>sklearn.semi_supervised</code> Semi-Supervised Learning . . . . .	1932
29.33 <code>sklearn.svm</code> : Support Vector Machines . . . . .	1938
29.34 <code>sklearn.tree</code> : Decision Trees . . . . .	1970
29.35 <code>sklearn.utils</code> : Utilities . . . . .	1991
29.36 Recently deprecated . . . . .	1995

## WELCOME TO SCIKIT-LEARN

### 1.1 Installing scikit-learn

---

**Note:** If you wish to contribute to the project, it's recommended you [install the latest development version](#).

---

#### 1.1.1 Installing the latest release

Scikit-learn requires:

- Python (>= 2.7 or >= 3.3),
- NumPy (>= 1.8.2),
- SciPy (>= 0.13.3).

If you already have a working installation of numpy and scipy, the easiest way to install scikit-learn is using pip

```
pip install -U scikit-learn
```

or conda:

```
conda install scikit-learn
```

If you have not installed NumPy or SciPy yet, you can also install these using conda or pip. When using pip, please ensure that *binary wheels* are used, and NumPy and SciPy are not recompiled from source, which can happen when using particular configurations of operating system and hardware (such as Linux on a Raspberry Pi). Building numpy and scipy from source can be complex (especially on Windows) and requires careful configuration to ensure that they link against an optimized implementation of linear algebra routines. Instead, use a third-party distribution as described below.

If you must install scikit-learn and its dependencies with pip, you can install it as `scikit-learn[alldeps]`. The most common use case for this is in a `requirements.txt` file used as part of an automated build process for a PaaS application or a Docker image. This option is not intended for manual installation from the command line.

#### 1.1.2 Third-party Distributions

If you don't already have a python installation with numpy and scipy, we recommend to install either via your package manager or via a python bundle. These come with numpy, scipy, scikit-learn, matplotlib and many other helpful

scientific and data processing libraries.

Available options are:

### Canopy and Anaconda for all supported platforms

Canopy and Anaconda both ship a recent version of scikit-learn, in addition to a large set of scientific python library for Windows, Mac OSX and Linux.

Anaconda offers scikit-learn as part of its free distribution.

**Warning:** To upgrade or uninstall scikit-learn installed with Anaconda or conda you **should not use the pip command**. Instead:

To upgrade scikit-learn:

```
conda update scikit-learn
```

To uninstall scikit-learn:

```
conda remove scikit-learn
```

Upgrading with `pip install -U scikit-learn` or uninstalling `pip uninstall scikit-learn` is likely fail to properly remove files installed by the `conda` command.

`pip` upgrade and uninstall operations only work on packages installed via `pip install`.

### WinPython for Windows

The WinPython project distributes scikit-learn as an additional plugin.

For installation instructions for particular operating systems or for compiling the bleeding edge version, see the [Advanced installation instructions](#).

## 1.2 Frequently Asked Questions

Here we try to give some answers to questions that regularly pop up on the mailing list.

### 1.2.1 What is the project name (a lot of people get it wrong)?

scikit-learn, but not scikit or SciKit nor sci-kit learn. Also not scikits.learn or scikits-learn, which were previously used.

### 1.2.2 How do you pronounce the project name?

sy-kit learn. sci stands for science!

### 1.2.3 Why scikit?

There are multiple scikits, which are scientific toolboxes built around SciPy. You can find a list at <https://scikits.appspot.com/scikits>. Apart from scikit-learn, another popular one is `scikit-image`.

## 1.2.4 How can I contribute to scikit-learn?

See [Contributing](#). Before wanting to add a new algorithm, which is usually a major and lengthy undertaking, it is recommended to start with known issues. Please do not contact the contributors of scikit-learn directly regarding contributing to scikit-learn.

## 1.2.5 What's the best way to get help on scikit-learn usage?

**For general machine learning questions**, please use [Cross Validated](#) with the [machine-learning] tag.

**For scikit-learn usage questions**, please use [Stack Overflow](#) with the [scikit-learn] and [python] tags. You can alternatively use the [mailing list](#).

Please make sure to include a minimal reproduction code snippet (ideally shorter than 10 lines) that highlights your problem on a toy dataset (for instance from `sklearn.datasets` or randomly generated with functions of `numpy.random` with a fixed random seed). Please remove any line of code that is not necessary to reproduce your problem.

The problem should be reproducible by simply copy-pasting your code snippet in a Python shell with scikit-learn installed. Do not forget to include the import statements.

More guidance to write good reproduction code snippets can be found at:

<http://stackoverflow.com/help/mcve>

If your problem raises an exception that you do not understand (even after googling it), please make sure to include the full traceback that you obtain when running the reproduction script.

For bug reports or feature requests, please make use of the [issue tracker on Github](#).

There is also a [scikit-learn Gitter channel](#) where some users and developers might be found.

**Please do not email any authors directly to ask for assistance, report bugs, or for any other issue related to scikit-learn.**

## 1.2.6 How can I create a bunch object?

Don't make a bunch object! They are not part of the scikit-learn API. Bunch objects are just a way to package some numpy arrays. As a scikit-learn user you only ever need numpy arrays to feed your model with data.

For instance to train a classifier, all you need is a 2D array `X` for the input variables and a 1D array `y` for the target variables. The array `X` holds the features as columns and samples as rows . The array `y` contains integer values to encode the class membership of each sample in `X`.

## 1.2.7 How can I load my own datasets into a format usable by scikit-learn?

Generally, scikit-learn works on any numeric data stored as numpy arrays or scipy sparse matrices. Other types that are convertible to numeric arrays such as pandas DataFrame are also acceptable.

For more information on loading your data files into these usable data structures, please refer to [loading external datasets](#).

## 1.2.8 What are the inclusion criteria for new algorithms ?

We only consider well-established algorithms for inclusion. A rule of thumb is at least 3 years since publication, 200+ citations and wide use and usefulness. A technique that provides a clear-cut improvement (e.g. an enhanced data structure or a more efficient approximation technique) on a widely-used method will also be considered for inclusion.

From the algorithms or techniques that meet the above criteria, only those which fit well within the current API of scikit-learn, that is a `fit`, `predict`/`transform` interface and ordinarily having input/output that is a numpy array or sparse matrix, are accepted.

The contributor should support the importance of the proposed addition with research papers and/or implementations in other similar packages, demonstrate its usefulness via common use-cases/applications and corroborate performance improvements, if any, with benchmarks and/or plots. It is expected that the proposed algorithm should outperform the methods that are already implemented in scikit-learn at least in some areas.

Also note that your implementation need not be in scikit-learn to be used together with scikit-learn tools. You can implement your favorite algorithm in a scikit-learn compatible way, upload it to github and let us know. We will list it under [Related Projects](#).

### 1.2.9 Why are you so selective on what algorithms you include in scikit-learn?

Code is maintenance cost, and we need to balance the amount of code we have with the size of the team (and add to this the fact that complexity scales non linearly with the number of features). The package relies on core developers using their free time to fix bugs, maintain code and review contributions. Any algorithm that is added needs future attention by the developers, at which point the original author might long have lost interest. Also see [this thread on the mailing list](#).

### 1.2.10 Why did you remove HMMs from scikit-learn?

See [Will you add graphical models or sequence prediction to scikit-learn?](#).

### 1.2.11 Will you add graphical models or sequence prediction to scikit-learn?

Not in the foreseeable future. scikit-learn tries to provide a unified API for the basic tasks in machine learning, with pipelines and meta-algorithms like grid search to tie everything together. The required concepts, APIs, algorithms and expertise required for structured learning are different from what scikit-learn has to offer. If we started doing arbitrary structured learning, we'd need to redesign the whole package and the project would likely collapse under its own weight.

There are two projects with API similar to scikit-learn that do structured prediction:

- `pystruct` handles general structured learning (focuses on SSVMs on arbitrary graph structures with approximate inference; defines the notion of sample as an instance of the graph structure)
- `seqlearn` handles sequences only (focuses on exact inference; has HMMs, but mostly for the sake of completeness; treats a feature vector as a sample and uses an offset encoding for the dependencies between feature vectors)

### 1.2.12 Will you add GPU support?

No, or at least not in the near future. The main reason is that GPU support will introduce many software dependencies and introduce platform specific issues. scikit-learn is designed to be easy to install on a wide variety of platforms. Outside of neural networks, GPUs don't play a large role in machine learning today, and much larger gains in speed can often be achieved by a careful choice of algorithms.

## 1.2.13 Do you support PyPy?

In case you didn't know, [PyPy](#) is the new, fast, just-in-time compiling Python implementation. We don't support it. When the [NumPy support](#) in PyPy is complete or near-complete, and SciPy is ported over as well, we can start thinking of a port. We use too much of NumPy to work with a partial implementation.

## 1.2.14 How do I deal with string data (or trees, graphs...)?

scikit-learn estimators assume you'll feed them real-valued feature vectors. This assumption is hard-coded in pretty much all of the library. However, you can feed non-numerical inputs to estimators in several ways.

If you have text documents, you can use a term frequency features; see [Text feature extraction](#) for the built-in *text vectorizers*. For more general feature extraction from any kind of data, see [Loading features from dicts](#) and [Feature hashing](#).

Another common case is when you have non-numerical data and a custom distance (or similarity) metric on these data. Examples include strings with edit distance (aka. Levenshtein distance; e.g., DNA or RNA sequences). These can be encoded as numbers, but doing so is painful and error-prone. Working with distance metrics on arbitrary data can be done in two ways.

Firstly, many estimators take precomputed distance/similarity matrices, so if the dataset is not too large, you can compute distances for all pairs of inputs. If the dataset is large, you can use feature vectors with only one “feature”, which is an index into a separate data structure, and supply a custom metric function that looks up the actual data in this data structure. E.g., to use DBSCAN with Levenshtein distances:

```
>>> from leven import levenshtein
>>> import numpy as np
>>> from sklearn.cluster import dbscan
>>> data = ["ACCTCTAGAAG", "ACCTACTAGAAGTT", "GAATATTAGGCCGA"]
>>> def lev_metric(x, y):
...     i, j = int(x[0]), int(y[0])      # extract indices
...     return levenshtein(data[i], data[j])
...
>>> X = np.arange(len(data)).reshape(-1, 1)
>>> X
array([[0],
       [1],
       [2]])
>>> dbscan(X, metric=lev_metric, eps=5, min_samples=2)
([0, 1], array([ 0,  0, -1]))
```

(This uses the third-party edit distance package `leven`.)

Similar tricks can be used, with some care, for tree kernels, graph kernels, etc.

## 1.2.15 Why do I sometime get a crash/freeze with n\_jobs > 1 under OSX or Linux?

Several scikit-learn tools such as `GridSearchCV` and `cross_val_score` rely internally on Python's *multiprocessing* module to parallelize execution onto several Python processes by passing `n_jobs > 1` as argument.

The problem is that Python *multiprocessing* does a `fork` system call without following it with an `exec` system call for performance reasons. Many libraries like (some versions of) Accelerate / vecLib under OSX, (some versions of) MKL, the OpenMP runtime of GCC, nvidia's Cuda (and probably many others), manage their own internal thread pool. Upon a call to `fork`, the thread pool state in the child process is corrupted: the thread pool believes it has many threads while only the main thread state has been forked. It is possible to change the libraries to make them detect

when a fork happens and reinitialize the thread pool in that case: we did that for OpenBLAS (merged upstream in master since 0.2.10) and we contributed a [patch](#) to GCC’s OpenMP runtime (not yet reviewed).

But in the end the real culprit is Python’s `multiprocessing` that does `fork` without `exec` to reduce the overhead of starting and using new Python processes for parallel computing. Unfortunately this is a violation of the POSIX standard and therefore some software editors like Apple refuse to consider the lack of fork-safety in Accelerate / vecLib as a bug.

In Python 3.4+ it is now possible to configure `multiprocessing` to use the ‘forkserver’ or ‘spawn’ start methods (instead of the default ‘fork’) to manage the process pools. To work around this issue when using scikit-learn, you can set the `JOBLIB_START_METHOD` environment variable to ‘forkserver’. However the user should be aware that using the ‘forkserver’ method prevents `joblib.Parallel` to call function interactively defined in a shell session.

If you have custom code that uses `multiprocessing` directly instead of using it via `joblib` you can enable the ‘forkserver’ mode globally for your program: Insert the following instructions in your main script:

```
import multiprocessing

# other imports, custom code, load data, define model...

if __name__ == '__main__':
    multiprocessing.set_start_method('forkserver')

# call scikit-learn utils with n_jobs > 1 here
```

You can find more default on the new start methods in the `multiprocessing` documentation.

## 1.2.16 Why is there no support for deep or reinforcement learning / Will there be support for deep or reinforcement learning in scikit-learn?

Deep learning and reinforcement learning both require a rich vocabulary to define an architecture, with deep learning additionally requiring GPUs for efficient computing. However, neither of these fit within the design constraints of scikit-learn; as a result, deep learning and reinforcement learning are currently out of scope for what scikit-learn seeks to achieve.

You can find more information about addition of gpu support at [Will you add GPU support?](#).

## 1.2.17 Why is my pull request not getting any attention?

The scikit-learn review process takes a significant amount of time, and contributors should not be discouraged by a lack of activity or review on their pull request. We care a lot about getting things right the first time, as maintenance and later change comes at a high cost. We rarely release any “experimental” code, so all of our contributions will be subject to high use immediately and should be of the highest quality possible initially.

Beyond that, scikit-learn is limited in its reviewing bandwidth; many of the reviewers and core developers are working on scikit-learn on their own time. If a review of your pull request comes slowly, it is likely because the reviewers are busy. We ask for your understanding and request that you not close your pull request or discontinue your work solely because of this reason.

## 1.2.18 How do I set a `random_state` for an entire execution?

For testing and replicability, it is often important to have the entire execution controlled by a single seed for the pseudo-random number generator used in algorithms that have a randomized component. Scikit-learn does not use its own global random state; whenever a `RandomState` instance or an integer random seed is not provided as an argument, it

relies on the numpy global random state, which can be set using `numpy.random.seed`. For example, to set an execution's numpy global random state to 42, one could execute the following in his or her script:

```
import numpy as np
np.random.seed(42)
```

However, a global random state is prone to modification by other code during execution. Thus, the only way to ensure replicability is to pass `RandomState` instances everywhere and ensure that both estimators and cross-validation splitters have their `random_state` parameter set.

## 1.3 Support

There are several ways to get in touch with the developers.

### 1.3.1 Mailing List

- The main mailing list is [scikit-learn](#).
- There is also a commit list [scikit-learn-commits](#), where updates to the main repository and test failures get notified.

### 1.3.2 User questions

- Some scikit-learn developers support users on StackOverflow using the [\[scikit-learn\]](#) tag.
- For general theoretical or methodological Machine Learning questions [stack exchange](#) is probably a more suitable venue.

In both cases please use a descriptive question in the title field (e.g. no “Please help with scikit-learn!” as this is not a question) and put details on what you tried to achieve, what were the expected results and what you observed instead in the details field.

Code and data snippets are welcome. Minimalistic (up to ~20 lines long) reproduction script very helpful.

Please describe the nature of your data and the how you preprocessed it: what is the number of samples, what is the number and type of features (i.d. categorical or numerical) and for supervised learning tasks, what target are you trying to predict: binary, multiclass (1 out of `n_classes`) or multilabel (`k` out of `n_classes`) classification or continuous variable regression.

### 1.3.3 Bug tracker

If you think you've encountered a bug, please report it to the issue tracker:

<https://github.com/scikit-learn/scikit-learn/issues>

Don't forget to include:

- steps (or better script) to reproduce,
- expected outcome,
- observed outcome or python (or gdb) tracebacks

To help developers fix your bug faster, please link to a <https://gist.github.com> holding a standalone minimalistic python script that reproduces your bug and optionally a minimalistic subsample of your dataset (for instance exported as CSV files using `numpy.savetxt`).

Note: gists are git cloneable repositories and thus you can use git to push datafiles to them.

### 1.3.4 IRC

Some developers like to hang out on channel `#scikit-learn` on `irc.freenode.net`.

If you do not have an IRC client or are behind a firewall this web client works fine: <http://webchat.freenode.net>

### 1.3.5 Documentation resources

This documentation is relative to 0.19.dev0. Documentation for other versions can be found here:

- [0.18](#)
- [0.17](#)
- [0.16](#)
- [0.15](#)

Printable pdf documentation for all versions can be found [here](#).

## 1.4 Related Projects

Projects implementing the scikit-learn estimator API are encouraged to use the [scikit-learn-contrib template](#) which facilitates best practices for testing and documenting estimators. The [scikit-learn-contrib GitHub organisation](#) also accepts high-quality contributions of repositories conforming to this template.

Below is a list of sister-projects, extensions and domain specific packages.

### 1.4.1 Interoperability and framework enhancements

These tools adapt scikit-learn for use with other technologies or otherwise enhance the functionality of scikit-learn's estimators.

#### Data formats

- [sklearn\\_pandas](#) bridge for scikit-learn pipelines and pandas data frame with dedicated transformers.

#### Auto-ML

- [auto-sklearn](#) An automated machine learning toolkit and a drop-in replacement for a scikit-learn estimator
- [TPOT](#) An automated machine learning toolkit that optimizes a series of scikit-learn operators to design a machine learning pipeline, including data and feature preprocessors as well as the estimators. Works as a drop-in replacement for a scikit-learn estimator.

#### Experimentation frameworks

- [PyMC](#) Bayesian statistical models and fitting algorithms.
- [REP](#) Environment for conducting data-driven research in a consistent and reproducible way

- [ML Frontend](#) provides dataset management and SVM fitting/prediction through web-based and programmatic interfaces.
- [Scikit-Learn Laboratory](#) A command-line wrapper around scikit-learn that makes it easy to run machine learning experiments with multiple learners and large feature sets.
- [Xcessiv](#) is a notebook-like application for quick, scalable, and automated hyperparameter tuning and stacked ensembling. Provides a framework for keeping track of model-hyperparameter combinations.

### Model inspection and visualisation

- [eli5](#) A library for debugging/inspecting machine learning models and explaining their predictions.
- [mlxtend](#) Includes model visualization utilities.
- [scikit-plot](#) A visualization library for quick and easy generation of common plots in data analysis and machine learning.
- [yellowbrick](#) A suite of custom matplotlib visualizers for scikit-learn estimators to support visual feature analysis, model selection, evaluation, and diagnostics.

### Model export for production

- [sklearn-pmml](#) Serialization of (some) scikit-learn estimators into PMML.
- [sklearn2pmml](#) Serialization of a wide variety of scikit-learn estimators and transformers into PMML with the help of [JPMMML-SkLearn](#) library.
- [sklearn-porter](#) Transpile trained scikit-learn models to C, Java, Javascript and others.
- [sklearn-compiledtrees](#) Generate a C++ implementation of the predict function for decision trees (and ensembles) trained by sklearn. Useful for latency-sensitive production environments.

## 1.4.2 Other estimators and tasks

Not everything belongs or is mature enough for the central scikit-learn project. The following are projects providing interfaces similar to scikit-learn for additional learning algorithms, infrastructures and tasks.

### Structured learning

- [Seqlearn](#) Sequence classification using HMMs or structured perceptron.
- [HMMLearn](#) Implementation of hidden markov models that was previously part of scikit-learn.
- [PyStruct](#) General conditional random fields and structured prediction.
- [pomegranate](#) Probabilistic modelling for Python, with an emphasis on hidden Markov models.
- [sklearn-crfsuite](#) Linear-chain conditional random fields ([CRFsuite](#) wrapper with sklearn-like API).

### Deep neural networks etc.

- [pylearn2](#) A deep learning and neural network library build on theano with scikit-learn like interface.
- [sklearn\\_theano](#) scikit-learn compatible estimators, transformers, and datasets which use Theano internally
- [nolearn](#) A number of wrappers and abstractions around existing neural network libraries
- [keras](#) Deep Learning library capable of running on top of either TensorFlow or Theano.
- [lasagne](#) A lightweight library to build and train neural networks in Theano.

### Broad scope

- [mlxtend](#) Includes a number of additional estimators as well as model visualization utilities.
- [sparkit-learn](#) Scikit-learn API and functionality for PySpark's distributed modelling.

## Other regression and classification

- [xgboost](#) Optimised gradient boosted decision tree library.
- [lightning](#) Fast state-of-the-art linear model solvers (SDCA, AdaGrad, SVRG, SAG, etc...).
- [py-earth](#) Multivariate adaptive regression splines
- [Kernel Regression](#) Implementation of Nadaraya-Watson kernel regression with automatic bandwidth selection
- [gplearn](#) Genetic Programming for symbolic regression tasks.
- [multiisotonic](#) Isotonic regression on multidimensional features.

## Decomposition and clustering

- [lda](#): Fast implementation of latent Dirichlet allocation in Cython which uses Gibbs sampling to sample from the true posterior distribution. (scikit-learn's `sklearn.decomposition.LatentDirichletAllocation` implementation uses variational inference to sample from a tractable approximation of a topic model's posterior distribution.)
- [Sparse Filtering](#) Unsupervised feature learning based on sparse-filtering
- [kmodes](#) k-modes clustering algorithm for categorical data, and several of its variations.
- [hdbscan](#) HDBSCAN and Robust Single Linkage clustering algorithms for robust variable density clustering.
- [spherecluster](#) Spherical K-means and mixture of von Mises Fisher clustering routines for data on the unit hyper-sphere.

## Pre-processing

- [categorical-encoding](#) A library of sklearn compatible categorical variable encoders.
- [imbalanced-learn](#) Various methods to under- and over-sample datasets.

## 1.4.3 Statistical learning with Python

Other packages useful for data analysis and machine learning.

- [Pandas](#) Tools for working with heterogeneous and columnar data, relational queries, time series and basic statistics.
- [theano](#) A CPU/GPU array processing framework geared towards deep learning research.
- [statsmodels](#) Estimating and analysing statistical models. More focused on statistical tests and less on prediction than scikit-learn.
- [Sacred](#) Tool to help you configure, organize, log and reproduce experiments
- [gensim](#) A library for topic modelling, document indexing and similarity retrieval
- [Seaborn](#) Visualization library based on matplotlib. It provides a high-level interface for drawing attractive statistical graphics.
- [Deep Learning](#) A curated list of deep learning software libraries.

## Domain specific packages

- [scikit-image](#) Image processing and computer vision in python.
- [Natural language toolkit \(nltk\)](#) Natural language processing and some machine learning.
- [NiLearn](#) Machine learning for neuro-imaging.

- [AstroML](#) Machine learning for astronomy.
- [MSMBuilder](#) Machine learning for protein conformational dynamics time series.

## 1.4.4 Snippets and tidbits

The [wiki](#) has more!

# 1.5 About us

This is a community effort, and as such many people have contributed to it over the years.

## 1.5.1 History

This project was started in 2007 as a Google Summer of Code project by David Cournapeau. Later that year, Matthieu Brucher started work on this project as part of his thesis.

In 2010 Fabian Pedregosa, Gael Varoquaux, Alexandre Gramfort and Vincent Michel of INRIA took leadership of the project and made the first public release, February the 1st 2010. Since then, several releases have appeared following a ~3 month cycle, and a thriving international community has been leading the development.

## 1.5.2 People

The following people have been core contributors to scikit-learn's development and maintenance:

- [Mathieu Blondel](#)
- [Matthieu Brucher](#)
- [Lars Buitinck](#)
- [David Cournapeau](#)
- [Noel Dawe](#)
- [Vincent Dubourg](#)
- [Edouard Duchesnay](#)
- [Tom Dupré la Tour](#)
- [Alexander Fabisch](#)
- [Virgile Fritsch](#)
- [Satra Ghosh](#)
- [Angel Soler Gollonet](#)
- [Chris Filo Gorgolewski](#)
- [Alexandre Gramfort](#)
- [Olivier Grisel](#)
- [Jaques Grobler](#)
- [Yaroslav Halchenko](#)
- [Brian Holt](#)
- [Arnaud Joly](#)
- [Thouis \(Ray\) Jones](#)
- [Kyle Kastner](#)
- [Manoj Kumar](#)
- [Robert Layton](#)
- [Wei Li](#)
- [Paolo Losi](#)
- [Gilles Louppe](#)

- Jan Hendrik Metzen
- Vincent Michel
- Jarrod Millman
- Andreas Müller (release manager)
- Vlad Niculae
- Joel Nothman
- Alexandre Passos
- Fabian Pedregosa
- Peter Prettenhofer
- Bertrand Thirion
- Jake VanderPlas
- Nelle Varoquaux
- Gael Varoquaux
- Ron Weiss

Please do not email the authors directly to ask for assistance or report issues. Instead, please see [What's the best way to ask questions about scikit-learn in the FAQ](#).

**See also:**

[How you can contribute to the project](#)

### 1.5.3 Citing scikit-learn

If you use scikit-learn in a scientific publication, we would appreciate citations to the following paper:

Scikit-learn: Machine Learning in Python, Pedregosa *et al.*, JMLR 12, pp. 2825–2830, 2011.

Bibtex entry:

```
@article{scikit-learn,
    title={Scikit-learn: Machine Learning in {P}ython},
    author={Pedregosa, F. and Varoquaux, G. and Gramfort, A. and Michel, V.
           and Thirion, B. and Grisel, O. and Blondel, M. and Prettenhofer, P.
           and Weiss, R. and Dubourg, V. and Vanderplas, J. and Passos, A. and
           Cournapeau, D. and Brucher, M. and Perrot, M. and Duchesnay, E.},
    journal={Journal of Machine Learning Research},
    volume={12},
    pages={2825--2830},
    year={2011}
}
```

If you want to cite scikit-learn for its API or design, you may also want to consider the following paper:

API design for machine learning software: experiences from the scikit-learn project, Buitinck *et al.*, 2013.

Bibtex entry:

```
@inproceedings{sklearn_api,
    author    = {Lars Buitinck and Gilles Louppe and Mathieu Blondel and
                Fabian Pedregosa and Andreas Mueller and Olivier Grisel and
                Vlad Niculae and Peter Prettenhofer and Alexandre Gramfort
                and Jaques Grobler and Robert Layton and Jake VanderPlas and

```

## 1.5.4 Artwork

High quality PNG and SVG logos are available in the [doc/logos/](#) source directory.

## 1.5.5 Funding

[INRIA](#) actively supports this project. It has provided funding for Fabian Pedregosa (2010-2012), Jaques Grobler (2012-2013) and Olivier Grisel (2013-2015) to work on this project full-time. It also hosts coding sprints and

other events.

Paris-Saclay Center for Data Science funded one

year for a developer to work on the project full-time (2014-2015).

[NYU Moore-Sloan Data Science Environment](#) funded Andreas Mueller (2014-2016) to work on this project. The Moore-Sloan Data Science Environment also funds several students to work on the project part-time.

NYU

Télécom ParisTech funds Manoj Kumar (2014), Tom Dupré la Tour

(2015), Raghav RV (2015-2016) and Thierry Guillemot (2016) to work on scikit-learn.

Columbia University funds Andreas Mueller since 2016. The following students were sponsored by Google to work on scikit-learn through the Google Summer of Code program.

- 2007 - David Cournapeau
- 2011 - Vlad Niculae
- 2012 - Vlad Niculae, Immanuel Bayer.
- 2013 - Kemal Eren, Nicolas Trésegny
- 2014 - Hamzeh Alsalhi, Issam Laradji, Maheshakya Wijewardena, Manoj Kumar.
- 2015 - Raghav RV, Wei Xue
- 2016 - Nelson Liu, YenChen Lin

It also provided funding for sprints and events around scikit-learn. If you would like to participate in the next Google Summer of code program, please see [this page](#).

The NeuroDebian project providing Debian packaging and contributions is supported by Dr. James V. Haxby (Dartmouth College).

The PSF helped find and manage funding for our 2011 Granada sprint. More information can be found [here](#) tinyclues funded the 2011 international Granada sprint.

### Donating to the project

If you are interested in donating to the project or to one of our code-sprints, you can use the *Paypal* button below or the NumFOCUS Donations Page (if you use the latter, please indicate that you are donating for the scikit-learn project).

All donations will be handled by NumFOCUS, a non-profit-organization which is managed by a board of Scipy community members. NumFOCUS's mission is to foster scientific computing software, in particular in Python. As a fiscal home of scikit-learn, it ensures that money is available when needed to keep the project funded and available while in compliance with tax regulations.

The received donations for the scikit-learn project mostly will go towards covering travel-expenses for code sprints, as well as towards the organization budget of the project<sup>1</sup>.

<sup>1</sup> Regarding the organization budget in particular, we might use some of the donated funds to pay for other project expenses such as DNS, hosting or continuous integration services.

## Notes

### The 2013 Paris international sprint

Fig. 1.1: IAP VII/19 - DYSCO

*For more information on this sprint, see [here](#)*

### 1.5.6 Infrastructure support

- We would like to thank [Rackspace](#) for providing us with a free [Rackspace Cloud](#) account to automatically build the documentation and the example gallery from for the development version of scikit-learn using [this tool](#).
- We would also like to thank [Shining Panda](#) for free CPU time on their Continuous Integration server.

## 1.6 Who is using scikit-learn?

### 1.6.1 Spotify

Scikit-learn provides a toolbox with solid implementations of a bunch of state-of-the-art models and makes it easy to plug them into existing applications. We've been using it quite a lot for music recommendations at Spotify and I think it's the most well-designed ML package I've seen so far.

Erik Bernhardsson, Engineering Manager Music Discovery & Machine Learning, Spotify

## 1.6.2 Inria

At INRIA, we use scikit-learn to support leading-edge basic research in many teams: Parietal for neuroimaging, Lear for computer vision, Visages for medical image analysis, Privatics for security. The project is a fantastic tool to address difficult applications of machine learning in an academic environment as it is performant and versatile, but all easy-to-use and well documented, which makes it well suited to grad students.

Gaël Varoquaux, research at Parietal

## 1.6.3 betaworks

Betaworks is a NYC-based startup studio that builds new products, grows companies, and invests in others. Over the past 8 years we've launched a handful of social data analytics-driven services, such as Bitly, Chartbeat, digg and Scale Model. Consistently the betaworks data science team uses Scikit-learn for a variety of tasks. From exploratory analysis, to product development, it is an essential part of our toolkit. Recent uses are included in [digg's new video recommender system](#), and Poncho's [dynamic heuristic subspace clustering](#).

Gilad Lotan, Chief Data Scientist

## 1.6.4 Evernote

**EVERNOTE** Building a classifier is typically an iterative process of exploring the data, selecting the features (the attributes of the data believed to be predictive in some way), training the models, and finally evaluating them. For many of these tasks, we relied on the excellent scikit-learn package for Python.

[Read more](#)

Mark Ayzenshtat, VP, Augmented Intelligence

## 1.6.5 Télécom ParisTech

At Telecom ParisTech, scikit-learn is used for hands-on sessions and home assignments in introductory and advanced machine learning courses. The classes are for undergrads and masters students. The

great benefit of scikit-learn is its fast learning curve that allows students to quickly start working on interesting and motivating problems.

Alexandre Gramfort, Assistant Professor

### 1.6.6 Booking.com

#### Booking.com

At Booking.com, we use machine learning algorithms for many different applications, such as recommending hotels and destinations to our customers, detecting fraudulent reservations, or scheduling our customer service agents. Scikit-learn is one of the tools we use when implementing standard algorithms for prediction tasks. Its API and documentations are excellent and make it easy to use. The scikit-learn developers do a great job of incorporating state of the art implementations and new algorithms into the package. Thus, scikit-learn provides convenient access to a wide spectrum of algorithms, and allows us to readily find the right tool for the right job.

Melanie Mueller, Data Scientist

### 1.6.7 AWeber

The scikit-learn toolkit is indispensable for the Data Analysis and Management team at AWeber. It allows us to do AWesome stuff we would not otherwise have the time or resources to accomplish. The documentation is excellent, allowing new engineers to quickly evaluate and apply many different algorithms to our data. The text feature extraction utilities are useful when working with the large volume of email content we have at AWeber. The RandomizedPCA implementation, along with Pipelining and FeatureUnions, allows us to develop complex machine learning algorithms efficiently and reliably.

Anyone interested in learning more about how AWeber deploys scikit-learn in a production environment should check out talks from PyData Boston by AWeber's Michael Becker available at [https://github.com/mdbecker/pydata\\_2013](https://github.com/mdbecker/pydata_2013)

Michael Becker, Software Engineer, Data Analysis and Management Ninjas

### 1.6.8 Yhat

The combination of consistent APIs, thorough documentation, and top notch implementation make scikit-learn our favorite machine learning package in Python. scikit-learn makes doing advanced analysis in Python accessible to anyone. At Yhat, we make it easy to integrate these models into your production applications. Thus eliminating the unnecessary dev time encountered productionizing analytical work.

Greg Lamp, Co-founder Yhat

## 1.6.9 Rangespan

The Python scikit-learn toolkit is a core tool in the data science group at Rangespan. Its large collection of well documented models and algorithms allow our team of data scientists to prototype fast and quickly iterate to find the right solution to our learning problems. We find that scikit-learn is not only the right tool for prototyping, but its careful and well tested implementation give us the confidence to run scikit-learn models in production.

Jurgen Van Gael, Data Science Director at Rangespan Ltd

## 1.6.10 Birchbox

At Birchbox, we face a range of machine learning problems typical to E-commerce: product recommendation, user clustering, inventory prediction, trends detection, etc. Scikit-learn lets us experiment with many models, especially in the exploration phase of a new project: the data can be passed around in a consistent way; models are easy to save and reuse; updates keep us informed of new developments from the pattern discovery research community. Scikit-learn is an important tool for our team, built the right way in the right language.

Thierry Bertin-Mahieux, Birchbox, Data Scientist

## 1.6.11 Bestofmedia Group

Scikit-learn is our #1 toolkit for all things machine learning at Bestofmedia. We use it for a variety of tasks (e.g. spam fighting, ad click prediction, various ranking models) thanks to the varied, state-of-the-art algorithm implementations packaged into it. In the lab it accelerates prototyping of complex pipelines. In production I can say it has proven to be robust and efficient enough to be deployed for business critical components.

Eustache Diemert, Lead Scientist Bestofmedia Group

## 1.6.12 Change.org

At change.org we automate the use of scikit-learn's RandomForestClassifier in our production systems to drive email targeting that reaches millions of users across the world each week. In the lab, scikit-learn's ease-of-use, performance, and overall variety of algorithms implemented has proved invaluable in giving us a single reliable source to turn to for our machine-learning needs.

Vijay Ramesh, Software Engineer in Data/science at Change.org

## 1.6.13 PHIMECA Engineering

**PHIMECA**

At PHIMECA Engineering, we use scikit-learn estimators as surrogates for expensive-to-evaluate numerical models (mostly but not exclusively finite-element mechanical models) for speeding up the intensive post-processing operations involved in our simulation-based decision making framework. Scikit-learn's fit/predict API together with its efficient cross-validation tools considerably eases the task of selecting the best-fit estimator. We are also using scikit-learn for illustrating concepts in our training sessions. Trainees are always impressed by the ease-of-use of scikit-learn despite the apparent theoretical complexity of machine learning.

Vincent Dubourg, PHIMECA Engineering, PhD Engineer

## 1.6.14 HowAboutWe

At HowAboutWe, scikit-learn lets us implement a wide array of machine learning techniques in analysis and in production, despite having a small team. We use scikit-learn's classification algorithms to predict user behavior, enabling us to (for example) estimate the value of leads from a given traffic source early in the lead's tenure on our site. Also, our users' profiles consist of primarily unstructured data (answers to open-ended questions), so we use scikit-learn's feature extraction and dimensionality reduction tools to translate these unstructured data into inputs for our matchmaking system.

Daniel Weitzenfeld, Senior Data Scientist at HowAboutWe

## 1.6.15 PeerIndex

At PeerIndex we use scientific methodology to build the Influence Graph - a unique dataset that allows us to identify who's really influential and in which context. To do this, we have to tackle a range of machine learning and predictive modeling problems. Scikit-learn has emerged as our primary tool for developing prototypes and making quick progress. From predicting missing data and classifying tweets to clustering communities of social media users, scikit-learn proved useful in a variety of applications. Its very intuitive interface and excellent compatibility with other python tools makes it an indispensable tool in our daily research efforts.

Ferenc Huszar - Senior Data Scientist at Peerindex

## 1.6.16 DataRobot

DataRobot is building next generation predictive analytics software to make data scientists more productive, and scikit-learn is an integral part of our system. The variety of machine learning techniques in combination with the solid implementations that scikit-learn offers makes it a one-stop-shopping library for machine learning in Python. Moreover, its consistent API, well-tested code and permissive licensing allow us to use it in a production environment. Scikit-learn has literally saved us years of work we would have had to do ourselves to bring our product to market.

Jeremy Achin, CEO & Co-founder DataRobot Inc.

## 1.6.17 OkCupid

We're using scikit-learn at OkCupid to evaluate and improve our matchmaking system. The range of features it has, especially preprocessing utilities, means we can use it for a wide variety of projects, and it's performant enough to handle the volume of data that we need to sort through. The documentation is really thorough, as well, which makes the library quite easy to use.

David Koh - Senior Data Scientist at OkCupid

## 1.6.18 Lovely

At Lovely, we strive to deliver the best apartment marketplace, with respect to our users and our listings. From understanding user behavior, improving data quality, and detecting fraud, scikit-learn is a

regular tool for gathering insights, predictive modeling and improving our product. The easy-to-read documentation and intuitive architecture of the API makes machine learning both explorable and accessible to a wide range of python developers. I'm constantly recommending that more developers and scientists try scikit-learn.

Simon Frid - Data Scientist, Lead at Lovely

### 1.6.19 Data Publica

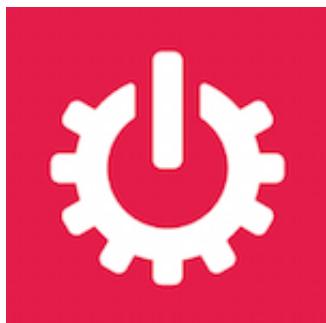

DATA PUBLICA

Data Publica builds a new predictive sales tool for commercial and marketing teams called C-Radar. We extensively use scikit-learn to build segmentations of customers through clustering, and to predict future customers based on past partnerships success or failure. We also categorize companies using their website communication thanks to scikit-learn and its machine learning algorithm implementations. Eventually, machine learning makes it possible to detect weak signals that traditional tools cannot see. All these complex tasks are performed in an easy and straightforward way thanks to the great quality of the scikit-learn framework.

Guillaume Lebougeois & Samuel Charron - Data Scientists at Data Publica

### 1.6.20 Machinalis

Scikit-learn is the cornerstone of all the machine learning projects carried at Machinalis. It has a consistent API, a wide selection of algorithms and lots of auxiliary tools to deal with the boilerplate. We have used it in production environments on a variety of projects including click-through rate prediction, [information extraction](#), and even counting sheep!

In fact, we use it so much that we've started to freeze our common use cases into Python packages, some of them open-sourced, like [FeatureForge](#). Scikit-learn in one word: Awesome.

Rafael Carrascosa, Lead developer

### 1.6.21 solido

Scikit-learn is helping to drive Moore's Law, via Solido. Solido creates computer-aided design tools used by the majority of top-20 semiconductor companies and fabs, to design the bleeding-edge chips inside smartphones, automobiles, and more. Scikit-learn helps to power Solido's algorithms for rare-event estimation, worst-case verification, optimization, and more. At Solido, we are particularly fond of scikit-learn's libraries for Gaussian Process models, large-scale regularized linear regression, and classification. Scikit-learn has increased our productivity, because for many ML problems we no longer need to "roll our own" code. [This PyData 2014 talk](#) has details.

Trent McConaghy, founder, Solido Design Automation Inc.

## 1.6.22 INFONEA

Comma Soft AG

We employ scikit-learn for rapid prototyping and custom-made Data Science solutions within our in-memory based Business Intelligence Software INFONEA®. As a well-documented and comprehensive collection of state-of-the-art algorithms and pipelining methods, scikit-learn enables us to provide flexible and scalable scientific analysis solutions. Thus, scikit-learn is immensely valuable in realizing a powerful integration of Data Science technology within self-service business analytics.

Thorsten Kranz, Data Scientist, Comma Soft AG.

## 1.6.23 Dataiku

Our software, Data Science Studio (DSS), enables users to create data services that combine ETL with Machine Learning. Our Machine Learning module integrates many scikit-learn algorithms. The scikit-learn library is a perfect integration with DSS because it offers algorithms for virtually all business cases. Our goal is to offer a transparent and flexible tool that makes it easier to optimize time consuming aspects of building a data service, preparing data, and training machine learning algorithms on all types of data.

Florian Douetteau, CEO, Dataiku

## 1.6.24 Otto Group

Here at Otto Group, one of global Big Five B2C online retailers, we are using scikit-learn in all aspects of our daily work from data exploration to development of machine learning application to the productive deployment of those services. It helps us to tackle machine learning problems ranging from e-commerce to logistics. Its consistent APIs enabled us to build the [Palladium REST-API framework](#) around it and continuously deliver scikit-learn based services.

Christian Rammig, Head of Data Science, Otto Group

## 1.6.25 Zopa

At Zopa, the first ever Peer-to-Peer lending platform, we extensively use scikit-learn to run the business and optimize our users' experience. It powers our Machine Learning models involved in credit risk, fraud risk, marketing, and pricing, and has been used for originating at least 1 billion GBP worth of Zopa loans. It is very well documented, powerful, and simple to use. We are grateful for the capabilities it has provided, and for allowing us to deliver on our mission of making money simple and fair.

Vlasios Vasileiou, Head of Data Science, Zopa

## 1.7 Release history

### 1.7.1 Version 0.19

#### In Development

##### Changed models

The following estimators and functions, when fit with the same data and parameters, may produce different models from the previous version. This often occurs due to changes in the modelling logic (bug fixes or enhancements), or in random sampling procedures.

- `sklearn.ensemble.IsolationForest` (bug fix)

Details are listed in the changelog below.

(While we are trying to better inform users by providing this information, we cannot assure that this list is complete.)

#### Changelog

#### New features

- Added the `neighbors.LocalOutlierFactor` class for anomaly detection based on nearest neighbors. #5279 by Nicolas Goix and Alexandre Gramfort.
- The new solver `mu` implements a Multiplicate Update in `decomposition.NMF`, allowing the optimization of all beta-divergences, including the Frobenius norm, the generalized Kullback-Leibler divergence and the Itakura-Saito divergence. By Tom Dupre la Tour.
- Added the `sklearn.model_selectionRepeatedKFold` and `sklearn.model_selectionRepeatedStratifiedKFold`. #8120 by Neeraj Gangwar.
- Added `metrics.mean_squared_log_error`, which computes the mean square error of the logarithmic transformation of targets, particularly useful for targets with an exponential trend. #7655 by Karan Desai.
- Added solver `saga` that implements the improved version of Stochastic Average Gradient, in `linear_model.LogisticRegression` and `linear_model.Ridge`. It allows the use of L1 penalty with multinomial logistic loss, and behaves marginally better than ‘sag’ during the first epochs of ridge and logistic regression. By Arthur Mensch.

#### Enhancements

- Update Sphinx-Gallery from 0.1.4 to 0.1.7 for resolving links in documentation build with Sphinx>1.5 #8010, #7986 Oscar Najera
- `multioutput.MultiOutputRegressor` and `multioutput.MultiOutputClassifier` now support online learning using `partial_fit`. issue: 8053 by Peng Yu.
- `pipeline.Pipeline` allows to cache transformers within a pipeline by using the `memory` constructor parameter. By #7990 by Guillaume Lemaitre.
- `decomposition.PCA`, `decomposition.IncrementalPCA` and `decomposition.TruncatedSVD` now expose the singular values from the underlying SVD. They are stored in the attribute `singular_values_`, like in `decomposition.IncrementalPCA`.

- `cluster.MiniBatchKMeans` and `cluster.KMeans` now uses significantly less memory when assigning data points to their nearest cluster center. #7721 by Jon Crall.
- Added `classes_` attribute to `model_selection.GridSearchCV`, `model_selection.RandomizedSearchCV`, `grid_search.GridSearchCV`, and `grid_search.RandomizedSearchCV` that matches the `classes_` attribute of `best_estimator_`. #7661 and #8295 by Alyssa Batula, Dylan Werner-Meier, and Stephen Hoover.
- Relax assumption on the data for the `SkewedChi2Sampler`. Since the Skewed-Chi2 kernel is defined on the open interval :math: (-skewness; +infty)^d, the transform function should not check whether `X < 0` but whether `X < -self.skewness`. (#7573) by ‘**Romain Brault**’.
- The `min_weight_fraction_leaf` constraint in tree construction is now more efficient, taking a fast path to declare a node a leaf if its weight is less than `2 * the minimum`. Note that the constructed tree will be different from previous versions where `min_weight_fraction_leaf` is used. #7441 by Nelson Liu.
- Added `average` parameter to perform weights averaging in `linear_model.PassiveAggressiveClassifier`. #4939 by Andrea Esuli.
- Custom metrics for the `sklearn.neighbors` binary trees now have fewer constraints: they must take two 1d-arrays and return a float. #6288 by Jake Vanderplas.
- `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor` now support sparse input for prediction. #6101 by Ibraim Ganiev.
- Added `shuffle` and `random_state` parameters to shuffle training data before taking prefixes of it based on training sizes in `model_selection.learning_curve`. #7506 by Narine Kokhlikyan.
- Added `norm_order` parameter to `feature_selection.SelectFromModel` to enable selection of the norm order when `coef_` is more than 1D
- Added `sample_weight` parameter to `pipeline.Pipeline.score`. #7723 by Mikhail Korobov.
- `check_estimator` now attempts to ensure that methods transform, predict, etc. do not set attributes on the estimator. #7533 by Ekaterina Krivich.
- For sparse matrices, `preprocessing.normalize` with `return_norm=True` will now raise a `NotImplementedError` with ‘l1’ or ‘l2’ norm and with norm ‘max’ the norms returned will be the same as for dense matrices. #7771 by Ang Lu.
- `sklearn.linear_model.RANSACRegressor` no longer throws an error when calling `fit` if no inliers are found in its first iteration. Furthermore, causes of skipped iterations are tracked in newly added attributes, `n_skips_*`. #7914 by Michael Horrell.
- `model_selection.cross_val_predict` now returns output of the correct shape for all values of the argument `method`. #7863 by Aman Dalmia.
- Fix a bug where `sklearn.feature_selection.SelectFdr` did not exactly implement Benjamini-Hochberg procedure. It formerly may have selected fewer features than it should. #7490 by Peng Meng.
- Added ability to set `n_jobs` parameter to `pipeline.make_union`. A `TypeError` will be raised for any other kwargs. #8028 by Alexander Booth.
- Added type checking to the `accept_sparse` parameter in `sklearn.utils.validation` methods. This parameter now accepts only boolean, string, or list/tuple of strings. `accept_sparse=None` is deprecated and should be replaced by `accept_sparse=False`. #7880 by Josh Karnofsky.

- `model_selection.GridSearchCV`, `model_selection.RandomizedSearchCV` and `model_selection.cross_val_score` now allow estimators with callable kernels which were previously prohibited. #8005 by Andreas Müller .
- Added ability to use sparse matrices in `feature_selection.f_regression` with `center=True`. #8065 by Daniel LeJeune.
- Add `sample_weight` parameter to `metrics.cohen_kappa_score` by Victor Poughon.
- In `gaussian_process.GaussianProcessRegressor`, method `predict` is a lot faster with `return_std=True` by Hadrien Bertrand.
- Added ability to use sparse matrices in `feature_selection.f_regression` with `center=True`. #8065 by Daniel LeJeune.
- `ensemble.VotingClassifier` now allow changing estimators by using `ensemble.VotingClassifier.set_params`. Estimators can also be removed by setting it to `None`. #7674 by Yichuan Liu.
- Prevent cast from float32 to float64 in

`sklearn.linear_model.LogisticRegression` when using newton-cg solver by Joan Massich

## Bug fixes

- Fixed a bug where `sklearn.ensemble.IsolationForest` uses an an incorrect formula for the average path length #8549 by Peter Wang.
- Fixed a bug where `sklearn.cluster.DBSCAN` gives incorrect result when input is a precomputed sparse matrix with initial rows all zero. #8306 by Akshay Gupta
- Fixed a bug where `sklearn.ensemble.AdaBoostClassifier` throws `ZeroDivisionError` while fitting data with single class labels. #7501 by Dominik Krzeminski.
- Fixed a bug where `sklearn.model_selection.BaseSearchCV.inverse_transform` returns `self.best_estimator_.transform()` instead of `self.best_estimator_.inverse_transform()` #8344 by Akshay Gupta
- Fixed same issue in `sklearn.grid_search.BaseSearchCV.inverse_transform` #8846 by Rasmus Eriksson
- Fixed a bug where `sklearn.linear_model.Ridgeless` and `sklearn.linear_model.RidgelessClassifier` breaks for sparse input. #8259 by Aman Dalmia.
- Fixed a bug where `sklearn.linear_model.RANSACRegressor.fit` may run until `max_iter` if finds a large inlier group early. #8251 by @aivision2020.
- Fixed a bug where `sklearn.datasets.make_moons` gives an incorrect result when `n_samples` is odd. #8198 by Josh Levy.
- Fixed a bug where `sklearn.linear_model.LassoLars` does not give the same result as the LassoLars implementation available in R (lars library). #7849 by Jair Montoya Martinez.
- Some `fetch_` functions in `sklearn.datasets` were ignoring the `download_if_missing` keyword. This was fixed in #7944 by Ralf Gommers.
- Fixed a bug in `sklearn.ensemble.GradientBoostingClassifier` and `sklearn.ensemble.GradientBoostingRegressor` where a float being compared to 0.0 using == caused a divide by zero error. This was fixed in #7970 by He Chen.
- Fix a bug regarding fitting `sklearn.cluster.KMeans` with a sparse array X and initial centroids, where X's means were unnecessarily being subtracted from the centroids. #7872 by Josh Karnofsky.

- Fix estimators to accept a `sample_weight` parameter of type `pandas.Series` in their `fit` function. #7825 by Kathleen Chen.
- Fixed a bug where `sklearn.ensemble.IsolationForest` fails when `max_features` is less than 1. #5732 by Ishank Gulati.
- Fix a bug where `sklearn.ensemble.VotingClassifier` raises an error when a numpy array is passed in for weights. #7983 by Vincent Pham.
- Fix a bug in `sklearn.decomposition.LatentDirichletAllocation` where the perplexity method was returning incorrect results because the `transform` method returns normalized document topic distributions as of version 0.18. #7954 by Gary Foreman.
- Fix a bug where `sklearn.ensemble.GradientBoostingClassifier` and `sklearn.ensemble.GradientBoostingRegressor` ignored the `min_impurity_split` parameter. #8006 by Sebastian Pölsterl.
- Fixes to the input validation in `sklearn.covariance.EllipticEnvelope`. #8086 by Andreas Müller.
- Fix output shape and bugs with `n_jobs > 1` in `sklearn.decomposition.SparseCoder` transform and `sklearn.decomposition.sparse_encode` for one-dimensional data and one component. This also impacts the output shape of `sklearn.decomposition.DictionaryLearning`. #8086 by Andreas Müller.
- Several fixes to input validation in `multiclass.OutputCodeClassifier` #8086 by Andreas Müller.
- Fix a bug where `sklearn.ensemble.gradient_boosting.QuantileLossFunction` computed negative errors for negative values of `ytrue - ypred` leading to wrong values when calling `__call__`. #8087 by Alexis Mignon
- Fix `sklearn.multioutput.MultiOutputClassifier.predict_proba` to return a list of 2d arrays, rather than a 3d array. In the case where different target columns had different numbers of classes, a `ValueError` would be raised on trying to stack matrices with different dimensions. #8093 by Peter Bull.
- Fix a bug where `sklearn.linear_model.LassoLars.fit` sometimes left `coef_` as a list, rather than an ndarray. #8160 by CJ Carey.
- Fix a bug in cases where `numpy.cumsum` may be numerically unstable, raising an exception if instability is identified. #7376 and #7331 by Joel Nothman and @yangarbiter.
- Fix a bug where `sklearn.base.BaseEstimator.__getstate__` obstructed pickling customizations of child-classes, when used in a multiple inheritance context. #8316 by Holger Peters.
- Fix a bug in `sklearn.metrics.classification._check_targets` which would return 'binary' if `y_true` and `y_pred` were both 'binary' but the union of `y_true` and `y_pred` was 'multiclass'. #8377 by Loic Esteve.
- Fix `sklearn.linear_model.BayesianRidge.fit` to return ridge parameter `alpha_` and `lambda_` consistent with calculated coefficients `coef_` and `intercept_`. #8224 by Peter Gedeck.
- Fixed a bug in `manifold.TSNE` where it stored the incorrect `k1_divergence_`. #6507 by Sebastian Saeger.
- Fixed a bug in `svm.OneClassSVM` where it returned floats instead of integer classes. #8676 by Vathsala Achar.
- Fixed a bug where `sklearn.tree.export_graphviz` raised an error when the length of `features_names` does not match `n_features` in the decision tree. #8512 by Li Li.
- Fixed a bug in `manifold.TSNE` affecting convergence of the gradient descent. #8768 by David DeTomaso.
- Fixed a memory leak in our LibLinear implementation. #9024 by Sergei Lebedev

## API changes summary

- Ensure that estimators' attributes ending with `_` are not set in the constructor but only in the `fit` method. Most notably, ensemble estimators (deriving from `ensemble.BaseEnsemble`) now only have `self.estimators_` available after `fit`. #7464 by Lars Buitinck and Loic Esteve.
- Deprecate the `doc_topic_distr` argument of the `perplexity` method in `sklearn.decomposition.LatentDirichletAllocation` because the user no longer has access to the unnormalized document topic distribution needed for the perplexity calculation. #7954 by Gary Foreman.
- Replace attribute `named_steps` dict to `sklearn.utils.Bunch` in `sklearn.pipeline.Pipeline` to enable tab completion in interactive environment. In the case conflict value on `named_steps` and `dict` attribute, `dict` behavior will be prioritized. #8481 by Herilalaina Rakotoarison.
- The `sklearn.multioutput.MultiOutputClassifier.predict_proba` function used to return a 3d array (`n_samples, n_classes, n_outputs`). In the case where different target columns had different numbers of classes, a `ValueError` would be raised on trying to stack matrices with different dimensions. This function now returns a list of arrays where the length of the list is `n_outputs`, and each array is (`n_samples, n_classes`) for that particular output. #8093 by Peter Bull.
- Deprecate the `fit_params` constructor input to the `sklearn.model_selection.GridSearchCV` and `sklearn.model_selection.RandomizedSearchCV` in favor of passing keyword parameters to the `fit` methods of those classes. Data-dependent parameters needed for model training should be passed as keyword arguments to `fit`, and conforming to this convention will allow the hyperparameter selection classes to be used with tools such as `sklearn.model_selection.cross_val_predict`. #2879 by Stephen Hoover.
- Gradient boosting base models are no longer estimators. By Andreas Müller.
- `feature_selection.SelectFromModel` now validates the `threshold` parameter and sets the `threshold_` attribute during the call to `fit`, and no longer during the call to `transform`, by Andreas Müller.
- `feature_selection.SelectFromModel` now has a `partial_fit` method only if the underlying estimator does. By Andreas Müller.
- `multiclass.OneVsRestClassifier` now has a `partial_fit` method only if the underlying estimator does. By Andreas Müller.
- Estimators with both methods `decision_function` and `predict_proba` are now required to have a monotonic relation between them. The method `check_decision_proba_consistency` has been added in `sklearn.utils.estimator_checks` to check their consistency. #7578 by Shubham Bhardwaj
- All tree based estimators now accept a `min_impurity_decrease` parameter in lieu of the `min_impurity_split`, which is now deprecated. The `min_impurity_decrease` helps stop splitting the nodes in which the weighted impurity decrease from splitting is no longer atleast `min_impurity_decrease`. #8449 by Raghav RV\_
- The `n_topics` parameter of `decomposition.LatentDirichletAllocation` has been renamed to `n_components` and will be removed in version 0.21. #8922 by :user:Attractadore
- SciPy  $\geq 0.13.3$  and NumPy  $\geq 1.8.2$  are now the minimum supported versions for scikit-learn. The following backported functions in `sklearn.utils` have been removed or deprecated accordingly. #8854 and #8874 by Naoya Kanai

Removed in 0.19:

- `utils.fixes.argmaxpartition`
- `utils.fixes.array_equal`
- `utils.fixes.astype`

- `utils.fixes.bincount`
- `utils.fixes.expit`
- `utils.fixes.frombuffer_empty`
- `utils.fixes.in1d`
- `utils.fixes.norm`
- `utils.fixes.rankdata`
- `utils.fixes.safe_copy`

Deprecated in 0.19, to be removed in 0.21:

- `utils.arpack.eigs`
- `utils.arpack.eigsh`
- `utils.arpack.svds`
- `utils.extmath.fast_dot`
- `utils.extmath.logsumexp`
- `utils.extmath.norm`
- `utils.extmath.pinvh`
- `utils.random.choice`
- `utils.sparsetools.connected_components`
- `utils.stats.rankdata`

## 1.7.2 Version 0.18.1

November 11, 2016

### Last release with Python 2.6 support

Scikit-learn 0.18 is the last major release of scikit-learn to support Python 2.6. Later versions of scikit-learn will require Python 2.7 or above.

### Changelog

#### Enhancements

- Improved `sample_without_replacement` speed by utilizing `numpy.random.permutation` for most cases. As a result, samples may differ in this release for a fixed random state. Affected estimators:

- `ensemble.BaggingClassifier`
- `ensemble.BaggingRegressor`
- `linear_model.RANSACRegressor`
- `model_selection.RandomizedSearchCV`
- `random_projection.SparseRandomProjection`

This also affects the `datasets.make_classification` method.

## Bug fixes

- Fix issue where `min_grad_norm` and `n_iter_without_progress` parameters were not being utilised by `manifold.TSNE`. #6497 by Sebastian Säger
- Fix bug for svm's decision values when `decision_function_shape` is `ovr` in `svm.SVC`. `svm.SVC`'s `decision_function` was incorrect from versions 0.17.0 through 0.18.0. #7724 by Bing Tian Dai
- Attribute `explained_variance_ratio` of `discriminant_analysis.LinearDiscriminantAnalysis` calculated with SVD and Eigen solver are now of the same length. #7632 by JPFrancoia
- Fixes issue in `Univariate feature selection` where score functions were not accepting multi-label targets. #7676 by Mohammed Affan
- Fixed setting parameters when calling `fit` multiple times on `feature_selection.SelectFromModel`. #7756 by Andreas Müller
- Fixes issue in `partial_fit` method of `multiclass.OneVsRestClassifier` when number of classes used in `partial_fit` was less than the total number of classes in the data. #7786 by Srivatsan Ramesh
- Fixes issue in `calibration.CalibratedClassifierCV` where the sum of probabilities of each class for a data was not 1, and `CalibratedClassifierCV` now handles the case where the training set has less number of classes than the total data. #7799 by Srivatsan Ramesh
- Fix a bug where `sklearn.feature_selection.SelectFdr` did not exactly implement Benjamini-Hochberg procedure. It formerly may have selected fewer features than it should. #7490 by Peng Meng.
- `sklearn.manifold.LocallyLinearEmbedding` now correctly handles integer inputs. #6282 by Jake Vanderplas.
- The `min_weight_fraction_leaf` parameter of tree-based classifiers and regressors now assumes uniform sample weights by default if the `sample_weight` argument is not passed to the `fit` function. Previously, the parameter was silently ignored. #7301 by Nelson Liu.
- Numerical issue with `linear_model.RidgeCV` on centered data when `n_features > n_samples`. #6178 by Bertrand Thirion
- Tree splitting criterion classes' cloning/pickling is now memory safe #7680 by Ibraim Ganiev.
- Fixed a bug where `decomposition.NMF` sets its `n_iters_` attribute in `transform()`. #7553 by Ekaterina Krivich.
- `sklearn.linear_model.LogisticRegressionCV` now correctly handles string labels. #5874 by Raghav RV.
- Fixed a bug where `sklearn.model_selection.train_test_split` raised an error when `stratify` is a list of string labels. #7593 by Raghav RV.
- Fixed a bug where `sklearn.model_selection.GridSearchCV` and `sklearn.model_selection.RandomizedSearchCV` were not pickleable because of a pickling bug in `np.ma.MaskedArray`. #7594 by Raghav RV.
- All cross-validation utilities in `sklearn.model_selection` now permit one time cross-validation splitters for the `cv` parameter. Also non-deterministic cross-validation splitters (where multiple calls to `split` produce dissimilar splits) can be used as `cv` parameter. The `sklearn.model_selection.GridSearchCV` will cross-validate each parameter setting on the split produced by the first `split` call to the cross-validation splitter. #7660 by Raghav RV.

## API changes summary

### Trees and forests

- The `min_weight_fraction_leaf` parameter of tree-based classifiers and regressors now assumes uniform sample weights by default if the `sample_weight` argument is not passed to the `fit` function. Previously, the parameter was silently ignored. #7301 by Nelson Liu.
- Tree splitting criterion classes' cloning/pickling is now memory safe. #7680 by Ibraim Ganiev.

### Linear, kernelized and related models

- Length of `explained_variance_ratio` of `discriminant_analysis`. `LinearDiscriminantAnalysis` changed for both Eigen and SVD solvers. The attribute has now a length of `min(n_components, n_classes - 1)`. #7632 by JPFrancoia
- Numerical issue with `linear_model.RidgeCV` on centered data when `n_features > n_samples`. #6178 by Bertrand Thirion

## 1.7.3 Version 0.18

September 28, 2016

### Last release with Python 2.6 support

Scikit-learn 0.18 will be the last version of scikit-learn to support Python 2.6. Later versions of scikit-learn will require Python 2.7 or above.

## Model Selection Enhancements and API Changes

### • The `model_selection` module

The new module `sklearn.model_selection`, which groups together the functionalities of formerly `sklearn.cross_validation`, `sklearn.grid_search` and `sklearn.learning_curve`, introduces new possibilities such as nested cross-validation and better manipulation of parameter searches with Pandas.

Many things will stay the same but there are some key differences. Read below to know more about the changes.

### • Data-independent CV splitters enabling nested cross-validation

The new cross-validation splitters, defined in the `sklearn.model_selection`, are no longer initialized with any data-dependent parameters such as `y`. Instead they expose a `split` method that takes in the data and yields a generator for the different splits.

This change makes it possible to use the cross-validation splitters to perform nested cross-validation, facilitated by `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` utilities.

### • The enhanced `cv_results_` attribute

The new `cv_results_` attribute (of `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV`) introduced in lieu of the `grid_scores_` attribute is a dict of 1D arrays with elements in each array corresponding to the parameter settings (i.e. search candidates).

The `cv_results_` dict can be easily imported into pandas as a DataFrame for exploring the search results.

The `cv_results_` arrays include scores for each cross-validation split (with keys such as `'split0_test_score'`), as well as their mean (`'mean_test_score'`) and standard deviation (`'std_test_score'`).

The ranks for the search candidates (based on their mean cross-validation score) is available at `cv_results_['rank_test_score']`.

The parameter values for each parameter is stored separately as numpy masked object arrays. The value, for that search candidate, is masked if the corresponding parameter is not applicable. Additionally a list of all the parameter dicts are stored at `cv_results_['params']`.

- **Parameters `n_folds` and `n_iter` renamed to `n_splits`**

Some parameter names have changed: The `n_folds` parameter in new `model_selection.KFold`, `model_selection.GroupKFold` (see below for the name change), and `model_selection.StratifiedKFold` is now renamed to `n_splits`. The `n_iter` parameter in `model_selection.ShuffleSplit`, the new class `model_selection.GroupShuffleSplit` and `model_selection.StratifiedShuffleSplit` is now renamed to `n_splits`.

- **Rename of splitter classes which accepts group labels along with data**

The cross-validation splitters `LabelKFold`, `LabelShuffleSplit`, `LeaveOneLabelOut` and `LeavePLabelOut` have been renamed to `model_selection.GroupKFold`, `model_selection.GroupShuffleSplit`, `model_selection.LeaveOneGroupOut` and `model_selection.LeavePGroupsOut` respectively.

Note the change from singular to plural form in `model_selection.LeavePGroupsOut`.

- **Fit parameter labels renamed to groups**

The `labels` parameter in the `split` method of the newly renamed splitters `model_selection.GroupKFold`, `model_selection.LeaveOneGroupOut`, `model_selection.LeavePGroupsOut`, `model_selection.GroupShuffleSplit` is renamed to `groups` following the new nomenclature of their class names.

- **Parameter `n_labels` renamed to `n_groups`**

The parameter `n_labels` in the newly renamed `model_selection.LeavePGroupsOut` is changed to `n_groups`.

- **Training scores and Timing information**

`cv_results_` also includes the training scores for each cross-validation split (with keys such as `'split0_train_score'`), as well as their mean (`'mean_train_score'`) and standard deviation (`'std_train_score'`). To avoid the cost of evaluating training score, set `return_train_score=False`.

Additionally the mean and standard deviation of the times taken to split, train and score the model across all the cross-validation splits is available at the key `'mean_time'` and `'std_time'` respectively.

## Changelog

### New features

#### Classifiers and Regressors

- The Gaussian Process module has been reimplemented and now offers classification and regression estimators through `gaussian_process.GaussianProcessClassifier` and `gaussian_process.GaussianProcessRegressor`. Among other things, the new implementation supports kernel engineering,

gradient-based hyperparameter optimization or sampling of functions from GP prior and GP posterior. Extensive documentation and examples are provided. By Jan Hendrik Metzen.

- Added new supervised learning algorithm: [Multi-layer Perceptron](#) #3204 by Issam H. Laradji
- Added [linear\\_model.HuberRegressor](#), a linear model robust to outliers. #5291 by Manoj Kumar.
- Added the [multioutput.MultiOutputRegressor](#) meta-estimator. It converts single output regressors to multi-output regressors by fitting one regressor per output. By Tim Head.

#### Other estimators

- New [mixture.GaussianMixture](#) and [mixture.BayesianGaussianMixture](#) replace former mixture models, employing faster inference for sounder results. #7295 by Wei Xue and Thierry Guillemot.
- Class [decomposition.RandomizedPCA](#) is now factored into [decomposition.PCA](#) and it is available calling with parameter `svd_solver='randomized'`. The default number of `n_iter` for 'randomized' has changed to 4. The old behavior of PCA is recovered by `svd_solver='full'`. An additional solver calls `arpack` and performs truncated (non-randomized) SVD. By default, the best solver is selected depending on the size of the input and the number of components requested. #5299 by Giorgio Patrini.
- Added two functions for mutual information estimation: [feature\\_selection.mutual\\_info\\_classif](#) and [feature\\_selection.mutual\\_info\\_regression](#). These functions can be used in [feature\\_selection.SelectKBest](#) and [feature\\_selection.SelectPercentile](#) as score functions. By Andrea Bravi and Nikolay Mayorov.
- Added the [ensemble.IsolationForest](#) class for anomaly detection based on random forests. By Nicolas Goix.
- Added algorithm="elkan" to [cluster.KMeans](#) implementing Elkan's fast K-Means algorithm. By Andreas Müller.

#### Model selection and evaluation

- Added [metrics.cluster.fowlkes\\_mallows\\_score](#), the Fowlkes Mallows Index which measures the similarity of two clusterings of a set of points By Arnaud Fouchet and Thierry Guillemot.
- Added [metrics.calinski\\_harabaz\\_score](#), which computes the Calinski and Harabaz score to evaluate the resulting clustering of a set of points. By Arnaud Fouchet and Thierry Guillemot.
- Added new cross-validation splitter [model\\_selection.TimeSeriesSplit](#) to handle time series data. #6586 by YenChen Lin
- The cross-validation iterators are replaced by cross-validation splitters available from [sklearn.model\\_selection](#), allowing for nested cross-validation. See [Model Selection Enhancements and API Changes](#) for more information. #4294 by Raghav RV.

## Enhancements

#### Trees and ensembles

- Added a new splitting criterion for [tree.DecisionTreeRegressor](#), the mean absolute error. This criterion can also be used in [ensemble.ExtraTreesRegressor](#), [ensemble.RandomForestRegressor](#), and the gradient boosting estimators. #6667 by Nelson Liu.
- Added weighted impurity-based early stopping criterion for decision tree growth. #6954 by Nelson Liu
- The random forest, extra tree and decision tree estimators now has a method `decision_path` which returns the decision path of samples in the tree. By Arnaud Joly.
- A new example has been added unveiling the decision tree structure. By Arnaud Joly.

- Random forest, extra trees, decision trees and gradient boosting estimator accept the parameter `min_samples_split` and `min_samples_leaf` provided as a percentage of the training samples. By [yelite](#) and [Arnaud Joly](#).
- Gradient boosting estimators accept the parameter `criterion` to specify the splitting criterion used in built decision trees. [#6667](#) by [Nelson Liu](#).
- The memory footprint is reduced (sometimes greatly) for `ensemble.Bagging` and classes that inherit from it, i.e., `ensemble.BaggingClassifier`, `ensemble.BaggingRegressor`, and `ensemble.IsolationForest`, by dynamically generating attribute `estimators_samples_` only when it is needed. By [David Staub](#).
- Added `n_jobs` and `sample_weight` parameters for `ensemble.VotingClassifier` to fit underlying estimators in parallel. [#5805](#) by [Ibraim Ganiev](#).

### Linear, kernelized and related models

- In `linear_model.LogisticRegression`, the SAG solver is now available in the multinomial case. [#5251](#) by [Tom Dupre la Tour](#).
- `linear_model.RANSACRegressor`, `svm.LinearSVC` and `svm.LinearSVR` now support `sample_weight`. By [Imaculate](#).
- Add parameter `loss` to `linear_model.RANSACRegressor` to measure the error on the samples for every trial. By [Manoj Kumar](#).
- Prediction of out-of-sample events with Isotonic Regression (`isotonic.IsotonicRegression`) is now much faster (over 1000x in tests with synthetic data). By [Jonathan Arfa](#).
- Isotonic regression (`isotonic.IsotonicRegression`) now uses a better algorithm to avoid  $O(n^2)$  behavior in pathological cases, and is also generally faster ([##6691](#)). By [Antony Lee](#).
- `naive_bayes.GaussianNB` now accepts data-independent class-priors through the parameter `priors`. By [Guillaume Lemaitre](#).
- `linear_model.ElasticNet` and `linear_model.Lasso` now works with `np.float32` input data without converting it into `np.float64`. This allows to reduce the memory consumption. [#6913](#) by [YenChen Lin](#).
- `semi_supervised.LabelPropagation` and `semi_supervised.LabelSpreading` now accept arbitrary kernel functions in addition to strings `knn` and `rbf`. [#5762](#) by [Utkarsh Upadhyay](#).

### Decomposition, manifold learning and clustering

- Added `inverse_transform` function to `decomposition.NMF` to compute data matrix of original shape. By [Anish Shah](#).
- `cluster.KMeans` and `cluster.MiniBatchKMeans` now works with `np.float32` and `np.float64` input data without converting it. This allows to reduce the memory consumption by using `np.float32`. [#6846](#) by [Sebastian Säger](#) and [YenChen Lin](#).

### Preprocessing and feature selection

- `preprocessing.RobustScaler` now accepts `quantile_range` parameter. [#5929](#) by [Konstantin Podshumok](#).
- `feature_extraction.FeatureHasher` now accepts string values. [#6173](#) by [Ryad Zenine](#) and [Devashish Deshpande](#).
- Keyword arguments can now be supplied to `func` in `preprocessing.FunctionTransformer` by means of the `kw_args` parameter. By [Brian McFee](#).
- `feature_selection.SelectKBest` and `feature_selection.SelectPercentile` now accept score functions that take `X, y` as input and return only the scores. By [Nikolay Mayorov](#).

## Model evaluation and meta-estimators

- `multiclass.OneVsOneClassifier` and `multiclass.OneVsRestClassifier` now support `partial_fit`. By Asish Panda and Philipp Dowling.
- Added support for substituting or disabling `pipeline.Pipeline` and `pipeline.FeatureUnion` components using the `set_params` interface that powers `sklearn.grid_search`. See [Selecting dimensionality reduction with Pipeline and GridSearchCV](#) By Joel Nothman and Robert McGibbon.
- The new `cv_results_` attribute of `model_selection.GridSearchCV` (and `model_selection.RandomizedSearchCV`) can be easily imported into pandas as a DataFrame. Ref [Model Selection Enhancements and API Changes](#) for more information. #6697 by Raghav RV.
- Generalization of `model_selection.cross_val_predict`. One can pass method names such as `predict_proba` to be used in the cross validation framework instead of the default `predict`. By Ori Ziv and Sears Merritt.
- The training scores and time taken for training followed by scoring for each search candidate are now available at the `cv_results_` dict. See [Model Selection Enhancements and API Changes](#) for more information. #7325 by Eugene Chen and Raghav RV.

## Metrics

- Added `labels` flag to `metrics.log_loss` to explicitly provide the labels when the number of classes in `y_true` and `y_pred` differ. #7239 by Hong Guangguo with help from Mads Jensen and Nelson Liu.
- Support sparse contingency matrices in cluster evaluation (`metrics.cluster.supervised`) to scale to a large number of clusters. #7419 by Gregory Stupp and Joel Nothman.
- Add `sample_weight` parameter to `metrics.matthews_corrcoef`. By Jatin Shah and Raghav RV.
- Speed up `metrics.silhouette_score` by using vectorized operations. By Manoj Kumar.
- Add `sample_weight` parameter to `metrics.confusion_matrix`. By Bernardo Stein.

## Miscellaneous

- Added `n_jobs` parameter to `feature_selection.RFECV` to compute the score on the test folds in parallel. By Manoj Kumar
- Codebase does not contain C/C++ cython generated files: they are generated during build. Distribution packages will still contain generated C/C++ files. By Arthur Mensch.
- Reduce the memory usage for 32-bit float input arrays of `utils.sparse_func.mean_variance_axis` and `utils.sparse_func.incr_mean_variance_axis` by supporting cython fused types. By YenChen Lin.
- The `ignore_warnings` now accept a category argument to ignore only the warnings of a specified type. By Thierry Guillemot.
- Added parameter `return_X_y` and return type `(data, target) : tuple` option to `load_iris` dataset #7049, `load_breast_cancer` dataset #7152, `load_digits` dataset, `load_diabetes` dataset, `load_linnerud` dataset, `load_boston` dataset #7154 by Manvendra Singh.
- Simplification of the `clone` function, deprecate support for estimators that modify parameters in `__init__`. #5540 by Andreas Müller.
- When unpickling a scikit-learn estimator in a different version than the one the estimator was trained with, a `UserWarning` is raised, see [the documentation on model persistence](#) for more details. (#7248) By Andreas Müller.

## Bug fixes

### Trees and ensembles

- Random forest, extra trees, decision trees and gradient boosting won't accept anymore `min_samples_split=1` as at least 2 samples are required to split a decision tree node. By Arnaud Joly
- `ensemble.VotingClassifier` now raises `NotFittedError` if `predict`, `transform` or `predict_proba` are called on the non-fitted estimator. by Sebastian Raschka.
- Fix bug where `ensemble.AdaBoostClassifier` and `ensemble.AdaBoostRegressor` would perform poorly if the `random_state` was fixed (#7411). By Joel Nothman.
- Fix bug in ensembles with randomization where the ensemble would not set `random_state` on base estimators in a pipeline or similar nesting. (#7411). Note, results for `ensemble.BaggingClassifier` `ensemble.BaggingRegressor`, `ensemble.AdaBoostClassifier` and `ensemble.AdaBoostRegressor` will now differ from previous versions. By Joel Nothman.

### Linear, kernelized and related models

- Fixed incorrect gradient computation for `loss='squared_epsilon_insensitive'` in `linear_model.SGDClassifier` and `linear_model.SGDRegressor` (#6764). By Wenhua Yang.
- Fix bug in `linear_model.LogisticRegressionCV` where `solver='liblinear'` did not accept `class_weights='balanced'`. (#6817). By Tom Dupre la Tour.
- Fix bug in `neighbors.RadiusNeighborsClassifier` where an error occurred when there were outliers being labelled and a weight function specified (#6902). By LeonieBorne.
- Fix `linear_model.ElasticNet` sparse decision function to match output with dense in the multioutput case.

### Decomposition, manifold learning and clustering

- `decomposition.RandomizedPCA` default number of `iterated_power` is 4 instead of 3. #5141 by Giorgio Patrini.
- `utils.extmath.randomized_svd` performs 4 power iterations by default, instead of 0. In practice this is enough for obtaining a good approximation of the true eigenvalues/vectors in the presence of noise. When `n_components` is small ( $< .1 * \min(X.shape)$ ) `n_iter` is set to 7, unless the user specifies a higher number. This improves precision with few components. #5299 by Giorgio Patrini.
- Whiten/non-whiten inconsistency between components of `decomposition.PCA` and `decomposition.RandomizedPCA` (now factored into PCA, see the New features) is fixed. `components_` are stored with no whitening. #5299 by Giorgio Patrini.
- Fixed bug in `manifold.spectral_embedding` where diagonal of unnormalized Laplacian matrix was incorrectly set to 1. #4995 by Peter Fischer.
- Fixed incorrect initialization of `utils.arpack.eigsh` on all occurrences. Affects `cluster.bicluster.SpectralBiclustering`, `decomposition.KernelPCA`, `manifold.LocallyLinearEmbedding`, and `manifold.SpectralEmbedding` (#5012). By Peter Fischer.
- Attribute `explained_variance_ratio_` calculated with the SVD solver of `discriminant_analysis.LinearDiscriminantAnalysis` now returns correct results. By JPFrancoia

### Preprocessing and feature selection

- `preprocessing.data._transform_selected` now always passes a copy of `X` to transform function when `copy=True` (#7194). By Caio Oliveira.

## Model evaluation and meta-estimators

- `model_selection.StratifiedKFold` now raises error if all `n_labels` for individual classes is less than `n_folds`. #6182 by Devashish Deshpande.
- Fixed bug in `model_selection.StratifiedShuffleSplit` where train and test sample could overlap in some edge cases, see #6121 for more details. By Loic Esteve.
- Fix in `sklearn.model_selection.StratifiedShuffleSplit` to return splits of size `train_size` and `test_size` in all cases (#6472). By Andreas Müller.
- Cross-validation of `OneVsOneClassifier` and `OneVsRestClassifier` now works with precomputed kernels. #7350 by Russell Smith.
- Fix incomplete `predict_proba` method delegation from `model_selection.GridSearchCV` to `linear_model.SGDClassifier` (#7159) by Yichuan Liu.

## Metrics

- Fix bug in `metrics.silhouette_score` in which clusters of size 1 were incorrectly scored. They should get a score of 0. By Joel Nothman.
- Fix bug in `metrics.silhouette_samples` so that it now works with arbitrary labels, not just those ranging from 0 to `n_clusters - 1`.
- Fix bug where expected and adjusted mutual information were incorrect if cluster contingency cells exceeded  $2^{**16}$ . By Joel Nothman.
- `metrics.pairwise.pairwise_distances` now converts arrays to boolean arrays when required in `scipy.spatial.distance`. #5460 by Tom Dupre la Tour.
- Fix sparse input support in `metrics.silhouette_score` as well as example examples/text/document\_clustering.py. By YenChen Lin.
- `metrics.roc_curve` and `metrics.precision_recall_curve` no longer round `y_score` values when creating ROC curves; this was causing problems for users with very small differences in scores (#7353).

## Miscellaneous

- `model_selection.tests._search._check_param_grid` now works correctly with all types that extends/implements `Sequence` (except string), including `range` (Python 3.x) and `xrange` (Python 2.x). #7323 by Viacheslav Kovalevskyi.
- `utils.extmath.randomized_range_finder` is more numerically stable when many power iterations are requested, since it applies LU normalization by default. If `n_iter < 2` numerical issues are unlikely, thus no normalization is applied. Other normalization options are available: 'none', 'LU' and 'QR'. #5141 by Giorgio Patrini.
- Fix a bug where some formats of `scipy.sparse` matrix, and estimators with them as parameters, could not be passed to `base.clone`. By Loic Esteve.
- `datasets.load_svmlight_file` now is able to read long int QID values. #7101 by Ibraim Ganiev.

## API changes summary

### Linear, kernelized and related models

- `residual_metric` has been deprecated in `linear_model.RANSACRegressor`. Use `loss` instead. By Manoj Kumar.
- Access to public attributes `.X_` and `.y_` has been deprecated in `isotonic.IsotonicRegression`. By Jonathan Arfa.

## Decomposition, manifold learning and clustering

- The old `mixture.DPGMM` is deprecated in favor of the new `mixture.BayesianGaussianMixture` (with the parameter `weight_concentration_prior_type='dirichlet_process'`). The new class solves the computational problems of the old class and computes the Gaussian mixture with a Dirichlet process prior faster than before. #7295 by Wei Xue and Thierry Guillemot.
- The old `mixture.VBGMM` is deprecated in favor of the new `mixture.BayesianGaussianMixture` (with the parameter `weight_concentration_prior_type='dirichlet_distribution'`). The new class solves the computational problems of the old class and computes the Variational Bayesian Gaussian mixture faster than before. #6651 by Wei Xue and Thierry Guillemot.
- The old `mixture.GMM` is deprecated in favor of the new `mixture.GaussianMixture`. The new class computes the Gaussian mixture faster than before and some of computational problems have been solved. #6666 by Wei Xue and Thierry Guillemot.

## Model evaluation and meta-estimators

- The `sklearn.cross_validation`, `sklearn.grid_search` and `sklearn.learning_curve` have been deprecated and the classes and functions have been reorganized into the `sklearn.model_selection` module. Ref [Model Selection Enhancements and API Changes](#) for more information. #4294 by Raghav RV.
- The `grid_scores_` attribute of `model_selection.GridSearchCV` and `model_selection.RandomizedSearchCV` is deprecated in favor of the attribute `cv_results_`. Ref [Model Selection Enhancements and API Changes](#) for more information. #6697 by Raghav RV.
- The parameters `n_iter` or `n_folds` in old CV splitters are replaced by the new parameter `n_splits` since it can provide a consistent and unambiguous interface to represent the number of train-test splits. #7187 by YenChen Lin.
- `classes` parameter was renamed to `labels` in `metrics.hamming_loss`. #7260 by Sebastián Vanrell.
- The splitter classes `LabelKFold`, `LabelShuffleSplit`, `LeaveOneLabelOut` and `LeavePLabelsOut` are renamed to `model_selection.GroupKFold`, `model_selection.GroupShuffleSplit`, `model_selection.LeaveOneGroupOut` and `model_selection.LeavePGroupsOut` respectively. Also the parameter `labels` in the `split` method of the newly renamed splitters `model_selection.LeaveOneGroupOut` and `model_selection.LeavePGroupsOut` is renamed to `groups`. Additionally in `model_selection.LeavePGroupsOut`, the parameter `n_labels` is renamed to `n_groups`. #6660 by Raghav RV.

## 1.7.4 Version 0.17.1

February 18, 2016

### Changelog

#### Bug fixes

- Upgrade vendored joblib to version 0.9.4 that fixes an important bug in `joblib.Parallel` that can silently yield to wrong results when working on datasets larger than 1MB: <https://github.com/joblib/joblib/blob/0.9.4/CHANGES.rst>
- Fixed reading of Bunch pickles generated with scikit-learn version  $\leq 0.16$ . This can affect users who have already downloaded a dataset with scikit-learn 0.16 and are loading it with scikit-learn 0.17. See [#6196](#) for how this affected `datasets.fetch_20newsgroups`. By [Loic Esteve](#).
- Fixed a bug that prevented using ROC AUC score to perform grid search on several CPU / cores on large arrays. See [#6147](#) By [Olivier Grisel](#).
- Fixed a bug that prevented to properly set the `presort` parameter in `ensemble.GradientBoostingRegressor`. See [#5857](#) By [Andrew McCulloh](#).
- Fixed a joblib error when evaluating the perplexity of a `decomposition.LatentDirichletAllocation` model. See [#6258](#) By [Chyi-Kwei Yau](#).

## 1.7.5 Version 0.17

November 5, 2015

## Changelog

### New features

- All the Scaler classes but `preprocessing.RobustScaler` can be fitted online by calling `partial_fit`. By Giorgio Patrini.
- The new class `ensemble.VotingClassifier` implements a “majority rule” / “soft voting” ensemble classifier to combine estimators for classification. By Sebastian Raschka.
- The new class `preprocessing.RobustScaler` provides an alternative to `preprocessing.StandardScaler` for feature-wise centering and range normalization that is robust to outliers. By Thomas Unterthiner.
- The new class `preprocessing.MaxAbsScaler` provides an alternative to `preprocessing.MinMaxScaler` for feature-wise range normalization when the data is already centered or sparse. By Thomas Unterthiner.
- The new class `preprocessing.FunctionTransformer` turns a Python function into a Pipeline-compatible transformer object. By Joe Jevnik.
- The new classes `cross_validation.LabelKFold` and `cross_validation.LabelShuffleSplit` generate train-test folds, respectively similar to `cross_validation.KFold` and `cross_validation.ShuffleSplit`, except that the folds are conditioned on a label array. By Brian McFee, Jean Kossaifi and Gilles Louppe.
- `decomposition.LatentDirichletAllocation` implements the Latent Dirichlet Allocation topic model with online variational inference. By Chyi-Kwei Yau, with code based on an implementation by Matt Hoffman. (#3659)
- The new solver `sag` implements a Stochastic Average Gradient descent and is available in both `linear_model.LogisticRegression` and `linear_model.Ridge`. This solver is very efficient for large datasets. By Danny Sullivan and Tom Dupre la Tour. (#4738)
- The new solver `cd` implements a Coordinate Descent in `decomposition.NMF`. Previous solver based on Projected Gradient is still available setting new parameter `solver` to `pg`, but is deprecated and will be removed in 0.19, along with `decomposition.ProjectedGradientNMF` and parameters `sparseness`, `eta`, `beta` and `nls_max_iter`. New parameters `alpha` and `l1_ratio` control L1 and L2 regularization, and `shuffle` adds a shuffling step in the `cd` solver. By Tom Dupre la Tour and Mathieu Blondel.

### Enhancements

- `manifold.TSNE` now supports approximate optimization via the Barnes-Hut method, leading to much faster fitting. By Christopher Erick Moody. (#4025)
- `cluster.mean_shift_.MeanShift` now supports parallel execution, as implemented in the `mean_shift` function. By Martino Sorbaro.
- `naive_bayes.GaussianNB` now supports fitting with `sample_weight`. By Jan Hendrik Metzen.
- `dummy.DummyClassifier` now supports a prior fitting strategy. By Arnaud Joly.
- Added a `fit_predict` method for `mixture.GMM` and subclasses. By Cory Lorenz.
- Added the `metrics.label_ranking_loss` metric. By Arnaud Joly.
- Added the `metrics.cohen_kappa_score` metric.
- Added a `warm_start` constructor parameter to the bagging ensemble models to increase the size of the ensemble. By Tim Head.

- Added option to use multi-output regression metrics without averaging. By Konstantin Shmelkov and Michael Eickenberg.
- Added `stratify` option to `cross_validation.train_test_split` for stratified splitting. By Miroslav Batchkarov.
- The `tree.export_graphviz` function now supports aesthetic improvements for `tree.DecisionTreeClassifier` and `tree.DecisionTreeRegressor`, including options for coloring nodes by their majority class or impurity, showing variable names, and using node proportions instead of raw sample counts. By Trevor Stephens.
- Improved speed of newton-cg solver in `linear_model.LogisticRegression`, by avoiding loss computation. By Mathieu Blondel and Tom Dupre la Tour.
- The `class_weight="auto"` heuristic in classifiers supporting `class_weight` was deprecated and replaced by the `class_weight="balanced"` option, which has a simpler formula and interpretation. By Hanna Wallach and Andreas Müller.
- Add `class_weight` parameter to automatically weight samples by class frequency for `linear_model.PassiveAgressiveClassifier`. By Trevor Stephens.
- Added backlinks from the API reference pages to the user guide. By Andreas Müller.
- The `labels` parameter to `sklearn.metrics.f1_score`, `sklearn.metrics.fbeta_score`, `sklearn.metrics.recall_score` and `sklearn.metrics.precision_score` has been extended. It is now possible to ignore one or more labels, such as where a multiclass problem has a majority class to ignore. By Joel Nothman.
- Add `sample_weight` support to `linear_model.RidgeClassifier`. By Trevor Stephens.
- Provide an option for sparse output from `sklearn.metrics.pairwise.cosine_similarity`. By Jaidev Deshpande.
- Add `minmax_scale` to provide a function interface for `MinMaxScaler`. By Thomas Unterthiner.
- `dump_svmlight_file` now handles multi-label datasets. By Chih-Wei Chang.
- RCV1 dataset loader (`sklearn.datasets.fetch_rcv1`). By Tom Dupre la Tour.
- The “Wisconsin Breast Cancer” classical two-class classification dataset is now included in scikit-learn, available with `sklearn.dataset.load_breast_cancer`.
- Upgraded to joblib 0.9.3 to benefit from the new automatic batching of short tasks. This makes it possible for scikit-learn to benefit from parallelism when many very short tasks are executed in parallel, for instance by the `grid_search.GridSearchCV` meta-estimator with `n_jobs > 1` used with a large grid of parameters on a small dataset. By Vlad Niculae, Olivier Grisel and Loic Esteve.
- For more details about changes in joblib 0.9.3 see the release notes: <https://github.com/joblib/joblib/blob/master/CHANGES.rst#release-093>
- Improved speed (3 times per iteration) of `decomposition.DictLearning` with coordinate descent method from `linear_model.Lasso`. By Arthur Mensch.
- Parallel processing (threaded) for queries of nearest neighbors (using the ball-tree) by Nikolay Mayorov.
- Allow `datasets.make_multilabel_classification` to output a sparse `y`. By Kashif Rasul.
- `cluster.DBSCAN` now accepts a sparse matrix of precomputed distances, allowing memory-efficient distance precomputation. By Joel Nothman.
- `tree.DecisionTreeClassifier` now exposes an `apply` method for retrieving the leaf indices samples are predicted as. By Daniel Galvez and Gilles Louppe.

- Speed up decision tree regressors, random forest regressors, extra trees regressors and gradient boosting estimators by computing a proxy of the impurity improvement during the tree growth. The proxy quantity is such that the split that maximizes this value also maximizes the impurity improvement. By Arnaud Joly, Jacob Schreiber and Gilles Louppe.
- Speed up tree based methods by reducing the number of computations needed when computing the impurity measure taking into account linear relationship of the computed statistics. The effect is particularly visible with extra trees and on datasets with categorical or sparse features. By Arnaud Joly.
- `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier` now expose an `apply` method for retrieving the leaf indices each sample ends up in under each try. By Jacob Schreiber.
- Add `sample_weight` support to `linear_model.LinearRegression`. By Sonny Hu. (#4881)
- Add `n_iter_without_progress` to `manifold.TSNE` to control the stopping criterion. By Santi Vilalba. (#5186)
- Added optional parameter `random_state` in `linear_model.Ridge`, to set the seed of the pseudo random generator used in sag solver. By Tom Dupre la Tour.
- Added optional parameter `warm_start` in `linear_model.LogisticRegression`. If set to True, the solvers `lbfgs`, `newton-cg` and `sag` will be initialized with the coefficients computed in the previous fit. By Tom Dupre la Tour.
- Added `sample_weight` support to `linear_model.LogisticRegression` for the `lbfgs`, `newton-cg`, and `sag` solvers. By Valentin Stolbunov. Support added to the liblinear solver. By Manoj Kumar.
- Added optional parameter `presort` to `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier`, keeping default behavior the same. This allows gradient boosters to turn off presorting when building deep trees or using sparse data. By Jacob Schreiber.
- Altered `metrics.roc_curve` to drop unnecessary thresholds by default. By Graham Clenaghan.
- Added `feature_selection.SelectFromModel` meta-transformer which can be used along with estimators that have `coef_` or `feature_importances_` attribute to select important features of the input data. By Maheshakya Wijewardena, Joel Nothman and Manoj Kumar.
- Added `metrics.pairwise.laplacian_kernel`. By Clyde Fare.
- `covariance.GraphLasso` allows separate control of the convergence criterion for the Elastic-Net subproblem via the `enet_tol` parameter.
- Improved verbosity in `decomposition.DictionaryLearning`.
- `ensemble.RandomForestClassifier` and `ensemble.RandomForestRegressor` no longer explicitly store the samples used in bagging, resulting in a much reduced memory footprint for storing random forest models.
- Added positive option to `linear_model.Lars` and `linear_model.lars_path` to force coefficients to be positive. (#5131)
- Added the `X_norm_squared` parameter to `metrics.pairwise.euclidean_distances` to provide precomputed squared norms for X.
- Added the `fit_predict` method to `pipeline.Pipeline`.
- Added the `preprocessing.min_max_scale` function.

## Bug fixes

- Fixed non-determinism in `dummy.DummyClassifier` with sparse multi-label output. By Andreas Müller.
- Fixed the output shape of `linear_model.RANSACRegressor` to `(n_samples, )`. By Andreas Müller.
- Fixed bug in `decomposition.DictLearning` when `n_jobs < 0`. By Andreas Müller.
- Fixed bug where `grid_search.RandomizedSearchCV` could consume a lot of memory for large discrete grids. By Joel Nothman.
- Fixed bug in `linear_model.LogisticRegressionCV` where `penalty` was ignored in the final fit. By Manoj Kumar.
- Fixed bug in `ensemble.forest.ForestClassifier` while computing `oob_score` and `X` is a sparse.csc\_matrix. By Ankur Ankan.
- All regressors now consistently handle and warn when given `y` that is of shape `(n_samples, 1)`. By Andreas Müller and Henry Lin. (#5431)
- Fix in `cluster.KMeans` cluster reassignment for sparse input by Lars Buitinck.
- Fixed a bug in `lda.LDA` that could cause asymmetric covariance matrices when using shrinkage. By Martin Billinger.
- Fixed `cross_validation.cross_val_predict` for estimators with sparse predictions. By Buddha Prakash.
- Fixed the `predict_proba` method of `linear_model.LogisticRegression` to use soft-max instead of one-vs-rest normalization. By Manoj Kumar. (#5182)
- Fixed the `partial_fit` method of `linear_model.SGDClassifier` when called with `average=True`. By Andrew Lamb. (#5282)
- Dataset fetchers use different filenames under Python 2 and Python 3 to avoid pickling compatibility issues. By Olivier Grisel. (#5355)
- Fixed a bug in `naive_bayes.GaussianNB` which caused classification results to depend on scale. By Jake Vanderplas.
- Fixed temporarily `linear_model.Ridge`, which was incorrect when fitting the intercept in the case of sparse data. The fix automatically changes the solver to ‘sag’ in this case. #5360 by Tom Dupre la Tour.
- Fixed a performance bug in `decomposition.RandomizedPCA` on data with a large number of features and fewer samples. (#4478) By Andreas Müller, Loic Esteve and Giorgio Patrini.
- Fixed bug in `cross_decomposition.PLS` that yielded unstable and platform dependent output, and failed on `fit_transform`. By Arthur Mensch.
- Fixes to the `Bunch` class used to store datasets.
- Fixed `ensemble.plot_partial_dependence` ignoring the `percentiles` parameter.
- Providing a set as vocabulary in `CountVectorizer` no longer leads to inconsistent results when pickling.
- Fixed the conditions on when a precomputed Gram matrix needs to be recomputed in `linear_model.LinearRegression`, `linear_model.OrthogonalMatchingPursuit`, `linear_model.Lasso` and `linear_model.ElasticNet`.
- Fixed inconsistent memory layout in the coordinate descent solver that affected `linear_model.DictionaryLearning` and `covariance.GraphLasso`. (#5337) By Olivier Grisel.
- `manifold.LocallyLinearEmbedding` no longer ignores the `reg` parameter.
- Nearest Neighbor estimators with custom distance metrics can now be pickled. (#4362)

- Fixed a bug in `pipeline.FeatureUnion` where `transformer_weights` were not properly handled when performing grid-searches.
- Fixed a bug in `linear_model.LogisticRegression` and `linear_model.LogisticRegressionCV` when using `class_weight='balanced'` or ``class_weight='auto'`. By Tom Dupre la Tour.
- Fixed bug #5495 when doing OVR(SVC(`decision_function_shape="ovr"`)). Fixed by Elvis Dohmatob.

## API changes summary

- Attribute `data_min`, `data_max` and `data_range` in `preprocessing.MinMaxScaler` are deprecated and won't be available from 0.19. Instead, the class now exposes `data_min_`, `data_max_` and `data_range_`. By Giorgio Patrini.
- All Scaler classes now have an `scale_` attribute, the feature-wise rescaling applied by their `transform` methods. The old attribute `std_` in `preprocessing.StandardScaler` is deprecated and superseded by `scale_`; it won't be available in 0.19. By Giorgio Patrini.
- `svm.SVC`` and `svm.NuSVC` now have an `decision_function_shape` parameter to make their decision function of shape (`n_samples`, `n_classes`) by setting `decision_function_shape='ovr'`. This will be the default behavior starting in 0.19. By Andreas Müller.
- Passing 1D data arrays as input to estimators is now deprecated as it caused confusion in how the array elements should be interpreted as features or as samples. All data arrays are now expected to be explicitly shaped (`n_samples`, `n_features`). By Vighnesh Birodkar.
- `lda.LDA` and `qda.QDA` have been moved to `discriminant_analysis.LinearDiscriminantAnalysis` and `discriminant_analysis.QuadraticDiscriminantAnalysis`.
- The `store_covariance` and `tol` parameters have been moved from the `fit` method to the constructor in `discriminant_analysis.LinearDiscriminantAnalysis` and the `store_covariances` and `tol` parameters have been moved from the `fit` method to the constructor in `discriminant_analysis.QuadraticDiscriminantAnalysis`.
- Models inheriting from `_LearntSelectorMixin` will no longer support the `transform` methods. (i.e, RandomForests, GradientBoosting, LogisticRegression, DecisionTrees, SVMs and SGD related models). Wrap these models around the metatransformer `feature_selection.SelectFromModel` to remove features (according to `coefs_` or `feature_importances_`) which are below a certain threshold value instead.
- `cluster.KMeans` re-runs cluster-assignments in case of non-convergence, to ensure consistency of `predict(X)` and `labels_`. By Vighnesh Birodkar.
- Classifier and Regressor models are now tagged as such using the `_estimator_type` attribute.
- Cross-validation iterators always provide indices into training and test set, not boolean masks.
- The `decision_function` on all regressors was deprecated and will be removed in 0.19. Use `predict` instead.
- `datasets.load_lfw_pairs` is deprecated and will be removed in 0.19. Use `datasets.fetch_lfw_pairs` instead.
- The deprecated `hmm` module was removed.
- The deprecated Bootstrap cross-validation iterator was removed.
- The deprecated Ward and WardAgglomerative classes have been removed. Use clustering. `AgglomerativeClustering` instead.
- `cross_validation.check_cv` is now a public function.

- The property `residues_` of `linear_model.LinearRegression` is deprecated and will be removed in 0.19.
- The deprecated `n_jobs` parameter of `linear_model.LinearRegression` has been moved to the constructor.
- Removed deprecated `class_weight` parameter from `linear_model.SGDClassifier`'s fit method. Use the `construction` parameter instead.
- The deprecated support for the sequence of sequences (or list of lists) multilabel format was removed. To convert to and from the supported binary indicator matrix format, use `MultiLabelBinarizer`.
- The behavior of calling the `inverse_transform` method of `Pipeline.pipeline` will change in 0.19. It will no longer reshape one-dimensional input to two-dimensional input.
- The deprecated attributes `indicator_matrix_`, `multilabel_` and `classes_` of `preprocessing.LabelBinarizer` were removed.
- Using `gamma=0` in `svm.SVC` and `svm.SVR` to automatically set the `gamma` to  $1. / n\_features$  is deprecated and will be removed in 0.19. Use `gamma="auto"` instead.

## 1.7.6 Version 0.16.1

April 14, 2015

## Changelog

### Bug fixes

- Allow input data larger than `block_size` in `covariance.LedoitWolf` by Andreas Müller.
- Fix a bug in `isotonic.IsotonicRegression` deduplication that caused unstable result in `calibration.CalibratedClassifierCV` by Jan Hendrik Metzen.
- Fix sorting of labels in `func:preprocessing.label_binarize` by Michael Heilman.
- Fix several stability and convergence issues in `cross_decomposition.CCA` and `cross_decomposition.PLSCanonical` by Andreas Müller
- Fix a bug in `cluster.KMeans` when `precompute_distances=False` on fortran-ordered data.
- Fix a speed regression in `ensemble.RandomForestClassifier`'s `predict` and `predict_proba` by Andreas Müller.
- Fix a regression where `utils.shuffle` converted lists and dataframes to arrays, by Olivier Grisel

## 1.7.7 Version 0.16

March 26, 2015

### Highlights

- Speed improvements (notably in `cluster.DBSCAN`), reduced memory requirements, bug-fixes and better default settings.
- Multinomial Logistic regression and a path algorithm in `linear_model.LogisticRegressionCV`.
- Out-of core learning of PCA via `decomposition.IncrementalPCA`.
- Probability calibration of classifiers using `calibration.CalibratedClassifierCV`.
- `cluster.Birch` clustering method for large-scale datasets.
- Scalable approximate nearest neighbors search with Locality-sensitive hashing forests in `neighbors.LSHForest`.
- Improved error messages and better validation when using malformed input data.
- More robust integration with pandas dataframes.

## Changelog

### New features

- The new `neighbors.LSHForest` implements locality-sensitive hashing for approximate nearest neighbors search. By Maheshakya Wijewardena.
- Added `svm.LinearSVR`. This class uses the liblinear implementation of Support Vector Regression which is much faster for large sample sizes than `svm.SVR` with linear kernel. By Fabian Pedregosa and Qiang Luo.
- Incremental fit for `GaussianNB`.
- Added `sample_weight` support to `dummy.DummyClassifier` and `dummy.DummyRegressor`. By Arnaud Joly.

- Added the `metrics.label_ranking_average_precision_score` metrics. By Arnaud Joly.
- Add the `metrics.coverage_error` metrics. By Arnaud Joly.
- Added `linear_model.LogisticRegressionCV`. By Manoj Kumar, Fabian Pedregosa, Gael Varoquaux and Alexandre Gramfort.
- Added `warm_start` constructor parameter to make it possible for any trained forest model to grow additional trees incrementally. By Laurent Dierer.
- Added `sample_weight` support to `ensemble.GradientBoostingClassifier` and `ensemble.GradientBoostingRegressor`. By Peter Prettenhofer.
- Added `decomposition.IncrementalPCA`, an implementation of the PCA algorithm that supports out-of-core learning with a `partial_fit` method. By Kyle Kastner.
- Averaged SGD for `SGDClassifier` and `SGDRegressor` By Danny Sullivan.
- Added `cross_val_predict` function which computes cross-validated estimates. By Luis Pedro Coelho
- Added `linear_model.TheilSenRegressor`, a robust generalized-median-based estimator. By Florian Wilhelm.
- Added `metrics.median_absolute_error`, a robust metric. By Gael Varoquaux and Florian Wilhelm.
- Add `cluster.Birch`, an online clustering algorithm. By Manoj Kumar, Alexandre Gramfort and Joel Nothman.
- Added shrinkage support to `discriminant_analysis.LinearDiscriminantAnalysis` using two new solvers. By Clemens Brunner and Martin Billinger.
- Added `kernel_ridge.KernelRidge`, an implementation of kernelized ridge regression. By Mathieu Blondel and Jan Hendrik Metzen.
- All solvers in `linear_model.Ridge` now support `sample_weight`. By Mathieu Blondel.
- Added `cross_validation.PredefinedSplit` cross-validation for fixed user-provided cross-validation folds. By Thomas Unterthiner.
- Added `calibration.CalibratedClassifierCV`, an approach for calibrating the predicted probabilities of a classifier. By Alexandre Gramfort, Jan Hendrik Metzen, Mathieu Blondel and Balazs Kegl.

## Enhancements

- Add option `return_distance` in `hierarchical.ward_tree` to return distances between nodes for both structured and unstructured versions of the algorithm. By Matteo Visconti di Oleggio Castello. The same option was added in `hierarchical.linkage_tree`. By Manoj Kumar
- Add support for sample weights in scorer objects. Metrics with sample weight support will automatically benefit from it. By Noel Dawe and Vlad Niculae.
- Added `newton-cg` and `lbfgs` solver support in `linear_model.LogisticRegression`. By Manoj Kumar.
- Add `selection="random"` parameter to implement stochastic coordinate descent for `linear_model.Lasso`, `linear_model.ElasticNet` and related. By Manoj Kumar.
- Add `sample_weight` parameter to `metrics.jaccard_similarity_score` and `metrics.log_loss`. By Jatin Shah.
- Support sparse multilabel indicator representation in `preprocessing.LabelBinarizer` and `multiclass.OneVsRestClassifier` (by Hamzeh Alsalhi with thanks to Rohit Sivaprasad), as well as evaluation metrics (by Joel Nothman).

- Add `sample_weight` parameter to `metrics.jaccard_similarity_score`. By [Jatin Shah](#).
- Add support for multiclass in `metrics.hinge_loss`. Added `labels=None` as optional parameter. By [Saurabh Jha](#).
- Add `sample_weight` parameter to `metrics.hinge_loss`. By [Saurabh Jha](#).
- Add `multi_class="multinomial"` option in `linear_model.LogisticRegression` to implement a Logistic Regression solver that minimizes the cross-entropy or multinomial loss instead of the default One-vs-Rest setting. Supports `lbfgs` and `newton-cg` solvers. By [Lars Buitinck](#) and [Manoj Kumar](#). Solver option `newton-cg` by [Simon Wu](#).
- `DictVectorizer` can now perform `fit_transform` on an iterable in a single pass, when giving the option `sort=False`. By [Dan Blanchard](#).
- `GridSearchCV` and `RandomizedSearchCV` can now be configured to work with estimators that may fail and raise errors on individual folds. This option is controlled by the `error_score` parameter. This does not affect errors raised on re-fit. By [Michał Romanik](#).
- Add `digits` parameter to `metrics.classification_report` to allow report to show different precision of floating point numbers. By [Ian Gilmore](#).
- Add a quantile prediction strategy to the `dummy.DummyRegressor`. By [Aaron Staple](#).
- Add `handle_unknown` option to `preprocessing.OneHotEncoder` to handle unknown categorical features more gracefully during transform. By [Manoj Kumar](#).
- Added support for sparse input data to decision trees and their ensembles. By [Fares Hedyati](#) and [Arnaud Joly](#).
- Optimized `cluster.AffinityPropagation` by reducing the number of memory allocations of large temporary data-structures. By [Antony Lee](#).
- Parallelization of the computation of feature importances in random forest. By [Olivier Grisel](#) and [Arnaud Joly](#).
- Add `n_iter_` attribute to estimators that accept a `max_iter` attribute in their constructor. By [Manoj Kumar](#).
- Added decision function for `multiclass.OneVsOneClassifier` By [Raghav RV](#) and [Kyle Beauchamp](#).
- `neighbors.kneighbors_graph` and `radius_neighbors_graph` support non-Euclidean metrics. By [Manoj Kumar](#)
- Parameter `connectivity` in `cluster.AgglomerativeClustering` and family now accept callables that return a connectivity matrix. By [Manoj Kumar](#).
- Sparse support for `paired_distances`. By [Joel Nothman](#).
- `cluster.DBSCAN` now supports sparse input and sample weights and has been optimized: the inner loop has been rewritten in Cython and radius neighbors queries are now computed in batch. By [Joel Nothman](#) and [Lars Buitinck](#).
- Add `class_weight` parameter to automatically weight samples by class frequency for `ensemble.RandomForestClassifier`, `tree.DecisionTreeClassifier`, `ensemble.ExtraTreesClassifier` and `tree.ExtraTreeClassifier`. By [Trevor Stephens](#).
- `grid_search.RandomizedSearchCV` now does sampling without replacement if all parameters are given as lists. By [Andreas Müller](#).
- Parallelized calculation of `pairwise_distances` is now supported for scipy metrics and custom callables. By [Joel Nothman](#).
- Allow the fitting and scoring of all clustering algorithms in `pipeline.Pipeline`. By [Andreas Müller](#).
- More robust seeding and improved error messages in `cluster.MeanShift` by [Andreas Müller](#).

- Make the stopping criterion for `mixture.GMM`, `mixture.DPGMM` and `mixture.VBGMM` less dependent on the number of samples by thresholding the average log-likelihood change instead of its sum over all samples. By [Hervé Bredin](#).
- The outcome of `manifold.spectral_embedding` was made deterministic by flipping the sign of eigenvectors. By [Hasil Sharma](#).
- Significant performance and memory usage improvements in `preprocessing.PolynomialFeatures`. By [Eric Martin](#).
- Numerical stability improvements for `preprocessing.StandardScaler` and `preprocessing.scale`. By [Nicolas Goix](#)
- `svm.SVC` fitted on sparse input now implements `decision_function`. By [Rob Zinkov](#) and [Andreas Müller](#).
- `cross_validation.train_test_split` now preserves the input type, instead of converting to numpy arrays.

## Documentation improvements

- Added example of using `FeatureUnion` for heterogeneous input. By [Matt Terry](#)
- Documentation on scorers was improved, to highlight the handling of loss functions. By [Matt Pico](#).
- A discrepancy between liblinear output and scikit-learn's wrappers is now noted. By [Manoj Kumar](#).
- Improved documentation generation: examples referring to a class or function are now shown in a gallery on the class/function's API reference page. By [Joel Nothman](#).
- More explicit documentation of sample generators and of data transformation. By [Joel Nothman](#).
- `sklearn.neighbors.BallTree` and `sklearn.neighbors.KDTree` used to point to empty pages stating that they are aliases of `BinaryTree`. This has been fixed to show the correct class docs. By [Manoj Kumar](#).
- Added silhouette plots for analysis of KMeans clustering using `metrics.silhouette_samples` and `metrics.silhouette_score`. See [Selecting the number of clusters with silhouette analysis on KMeans clustering](#)

## Bug fixes

- Metaestimators now support ducktyping for the presence of `decision_function`, `predict_proba` and other methods. This fixes behavior of `grid_search.GridSearchCV`, `grid_search.RandomizedSearchCV`, `pipeline.Pipeline`, `feature_selection.RFE`, `feature_selection.RFECV` when nested. By [Joel Nothman](#)
- The `scoring` attribute of grid-search and cross-validation methods is no longer ignored when a `grid_search.GridSearchCV` is given as a base estimator or the base estimator doesn't have `predict`.
- The function `hierarchical.ward_tree` now returns the children in the same order for both the structured and unstructured versions. By [Matteo Visconti di Oleggio Castello](#).
- `feature_selection.RFECV` now correctly handles cases when `step` is not equal to 1. By [Nikolay Mayorov](#)
- The `decomposition.PCA` now undoes whitening in its `inverse_transform`. Also, its `components_` now always have unit length. By [Michael Eickenberg](#).
- Fix incomplete download of the dataset when `datasets.download_20newsgroups` is called. By [Manoj Kumar](#).

- Various fixes to the Gaussian processes subpackage by Vincent Dubourg and Jan Hendrik Metzen.
- Calling `partial_fit` with `class_weight=='auto'` throws an appropriate error message and suggests a work around. By Danny Sullivan.
- `RBFSampler` with `gamma=g` formerly approximated `rbf_kernel` with `gamma=g/2`; the definition of `gamma` is now consistent, which may substantially change your results if you use a fixed value. (If you cross-validated over `gamma`, it probably doesn't matter too much.) By Dougal Sutherland.
- Pipeline object delegate the `classes_` attribute to the underlying estimator. It allows, for instance, to make bagging of a pipeline object. By Arnaud Joly
- `neighbors.NearestCentroid` now uses the median as the centroid when metric is set to `manhattan`. It was using the mean before. By Manoj Kumar
- Fix numerical stability issues in `linear_model.SGDClassifier` and `linear_model.SGDRegressor` by clipping large gradients and ensuring that weight decay rescaling is always positive (for large l2 regularization and large learning rate values). By Olivier Grisel
- When `compute_full_tree` is set to “auto”, the full tree is built when `n_clusters` is high and is early stopped when `n_clusters` is low, while the behavior should be vice-versa in `cluster.AgglomerativeClustering` (and friends). This has been fixed By Manoj Kumar
- Fix lazy centering of data in `linear_model.enet_path` and `linear_model.lasso_path`. It was centered around one. It has been changed to be centered around the origin. By Manoj Kumar
- Fix handling of precomputed affinity matrices in `cluster.AgglomerativeClustering` when using connectivity constraints. By Cathy Deng
- Correct `partial_fit` handling of `class_prior` for `sklearn.naive_bayes.MultinomialNB` and `sklearn.naive_bayes.BernoulliNB`. By Trevor Stephens.
- Fixed a crash in `metrics.precision_recall_fscore_support` when using unsorted `labels` in the multi-label setting. By Andreas Müller.
- Avoid skipping the first nearest neighbor in the methods `radius_neighbors`, `kneighbors`, `kneighbors_graph` and `radius_neighbors_graph` in `sklearn.neighbors.NearestNeighbors` and family, when the query data is not the same as fit data. By Manoj Kumar.
- Fix log-density calculation in the `mixture.GMM` with tied covariance. By Will Dawson
- Fixed a scaling error in `feature_selection.SelectFdr` where a factor `n_features` was missing. By Andrew Tulloch
- Fix zero division in `neighbors.KNeighborsRegressor` and related classes when using distance weighting and having identical data points. By Garret-R.
- Fixed round off errors with non positive-definite covariance matrices in GMM. By Alexis Mignon.
- Fixed a error in the computation of conditional probabilities in `naive_bayes.BernoulliNB`. By Hanna Wallach.
- Make the method `radius_neighbors` of `neighbors.NearestNeighbors` return the samples lying on the boundary for `algorithm='brute'`. By Yan Yi.
- Flip sign of `dual_coef_` of `svm.SVC` to make it consistent with the documentation and `decision_function`. By Artem Sobolev.
- Fixed handling of ties in `isotonic.IsotonicRegression`. We now use the weighted average of targets (secondary method). By Andreas Müller and Michael Bommarito.

## API changes summary

- `GridSearchCV` and `cross_val_score` and other meta-estimators don't convert pandas DataFrames into arrays any more, allowing DataFrame specific operations in custom estimators.
- `multiclass.fit_ovr`, `multiclass.predict_ovr`, `predict_proba_ovr`, `multiclass.fit_ovo`, `multiclass.predict_ovo`, `multiclass.fit_ecoc` and `multiclass.predict_ecoc` are deprecated. Use the underlying estimators instead.
- Nearest neighbors estimators used to take arbitrary keyword arguments and pass these to their distance metric. This will no longer be supported in scikit-learn 0.18; use the `metric_params` argument instead.
- **`n_jobs` parameter of the fit method shifted to the constructor of the `LinearRegression` class.**
- The `predict_proba` method of `multiclass.OneVsRestClassifier` now returns two probabilities per sample in the multiclass case; this is consistent with other estimators and with the method's documentation, but previous versions accidentally returned only the positive probability. Fixed by Will Lamond and [Lars Buitinck](#).
- Change default value of `precompute` in `ElasticNet` and `Lasso` to `False`. Setting `precompute` to "auto" was found to be slower when `n_samples > n_features` since the computation of the Gram matrix is computationally expensive and outweighs the benefit of fitting the Gram for just one alpha. `precompute="auto"` is now deprecated and will be removed in 0.18 By [Manoj Kumar](#).
- Expose `positive` option in `linear_model.enet_path` and `linear_model.lasso_path` which constrains coefficients to be positive. By [Manoj Kumar](#).
- Users should now supply an explicit average parameter to `sklearn.metrics.f1_score`, `sklearn.metrics.fbeta_score`, `sklearn.metrics.recall_score` and `sklearn.metrics.precision_score` when performing multiclass or multilabel (i.e. not binary) classification. By [Joel Nothman](#).
- `scoring` parameter for cross validation now accepts '`f1_micro`', '`f1_macro`' or '`f1_weighted`'. '`f1`' is now for binary classification only. Similar changes apply to '`precision`' and '`recall`'. By [Joel Nothman](#).
- The `fit_intercept`, `normalize` and `return_models` parameters in `linear_model.enet_path` and `linear_model.lasso_path` have been removed. They were deprecated since 0.14
- From now onwards, all estimators will uniformly raise `NotFittedError` (`utils.validation.NotFittedError`), when any of the `predict` like methods are called before the model is fit. By [Raghav RV](#).
- Input data validation was refactored for more consistent input validation. The `check_arrays` function was replaced by `check_array` and `check_X_y`. By [Andreas Müller](#).
- Allow `X=None` in the methods `radius_neighbors`, `kneighbors`, `kneighbors_graph` and `radius_neighbors_graph` in `sklearn.neighbors.NearestNeighbors` and family. If set to `None`, then for every sample this avoids setting the sample itself as the first nearest neighbor. By [Manoj Kumar](#).
- Add parameter `include_self` in `neighbors.kneighbors_graph` and `neighbors.radius_neighbors_graph` which has to be explicitly set by the user. If set to `True`, then the sample itself is considered as the first nearest neighbor.
- `thresh` parameter is deprecated in favor of new `tol` parameter in GMM, DPGMM and VBGMM. See *Enhancements* section for details. By [Hervé Bredin](#).
- Estimators will treat input with `dtype` object as numeric when possible. By [Andreas Müller](#)
- Estimators now raise `ValueError` consistently when fitted on empty data (less than 1 sample or less than 1 feature for 2D input). By [Olivier Grisel](#).

- The `shuffle` option of `linear_model.SGDClassifier`, `linear_model.SGDRegressor`, `linear_model.Perceptron`, `linear_model.PassiveAgressiveClassifier` and `linear_model.PassiveAgressiveRegressor` now defaults to True.
- `cluster.DBSCAN` now uses a deterministic initialization. The `random_state` parameter is deprecated. By Erich Schubert.

## 1.7.8 Version 0.15.2

September 4, 2014

### Bug fixes

- Fixed handling of the `p` parameter of the Minkowski distance that was previously ignored in nearest neighbors models. By [Nikolay Mayorov](#).
- Fixed duplicated alphas in `linear_model.LassoLars` with early stopping on 32 bit Python. By [Olivier Grisel](#) and [Fabian Pedregosa](#).
- Fixed the build under Windows when scikit-learn is built with MSVC while NumPy is built with MinGW. By [Olivier Grisel](#) and [Federico Vaggi](#).
- Fixed an array index overflow bug in the coordinate descent solver. By [Gael Varoquaux](#).
- Better handling of numpy 1.9 deprecation warnings. By [Gael Varoquaux](#).
- Removed unnecessary data copy in `cluster.KMeans`. By [Gael Varoquaux](#).
- Explicitly close open files to avoid ResourceWarnings under Python 3. By [Calvin Giles](#).

- The transform of `discriminant_analysis.LinearDiscriminantAnalysis` now projects the input on the most discriminant directions. By Martin Billinger.
- Fixed potential overflow in `_tree.safe_realloc` by Lars Buitinck.
- Performance optimization in `isotonic.IsotonicRegression`. By Robert Bradshaw.
- `nose` is no longer a runtime dependency to import `sklearn`, only for running the tests. By Joel Nothman.
- Many documentation and website fixes by Joel Nothman, Lars Buitinck Matt Pico, and others.

## 1.7.9 Version 0.15.1

August 1, 2014

### Bug fixes

- Made `cross_validation.cross_val_score` use `cross_validation.KFold` instead of `cross_validation.StratifiedKFold` on multi-output classification problems. By Nikolay Mayorov.
- Support unseen labels `preprocessing.LabelBinarizer` to restore the default behavior of 0.14.1 for backward compatibility. By Hamzeh Alsalhi.
- Fixed the `cluster.KMeans` stopping criterion that prevented early convergence detection. By Edward Raff and Gael Varoquaux.
- Fixed the behavior of `multiclass.OneVsOneClassifier`. in case of ties at the per-class vote level by computing the correct per-class sum of prediction scores. By Andreas Müller.
- Made `cross_validation.cross_val_score` and `grid_search.GridSearchCV` accept Python lists as input data. This is especially useful for cross-validation and model selection of text processing pipelines. By Andreas Müller.
- Fixed data input checks of most estimators to accept input data that implements the NumPy `__array__` protocol. This is the case for `pandas.Series` and `pandas.DataFrame` in recent versions of pandas. By Gael Varoquaux.
- Fixed a regression for `linear_model.SGDClassifier` with `class_weight="auto"` on data with non-contiguous labels. By Olivier Grisel.

## 1.7.10 Version 0.15

July 15, 2014

### Highlights

- Many speed and memory improvements all across the code
- Huge speed and memory improvements to random forests (and extra trees) that also benefit better from parallel computing.
- Incremental fit to `BernoulliRBM`
- Added `cluster.AgglomerativeClustering` for hierarchical agglomerative clustering with average linkage, complete linkage and ward strategies.
- Added `linear_model.RANSACRegressor` for robust regression models.

- Added dimensionality reduction with `manifold.TSNE` which can be used to visualize high-dimensional data.

## Changelog

### New features

- Added `ensemble.BaggingClassifier` and `ensemble.BaggingRegressor` meta-estimators for ensembling any kind of base estimator. See the *Bagging* section of the user guide for details and examples. By [Gilles Louppe](#).
- New unsupervised feature selection algorithm `feature_selection.VarianceThreshold`, by [Lars Buitinck](#).
- Added `linear_model.RANSACRegressor` meta-estimator for the robust fitting of regression models. By [Johannes Schönberger](#).
- Added `cluster.AgglomerativeClustering` for hierarchical agglomerative clustering with average linkage, complete linkage and ward strategies, by [Nelle Varoquaux](#) and [Gael Varoquaux](#).
- Shorthand constructors `pipeline.make_pipeline` and `pipeline.make_union` were added by [Lars Buitinck](#).
- Shuffle option for `cross_validation.StratifiedKFold`. By [Jeffrey Blackburne](#).
- Incremental learning (`partial_fit`) for Gaussian Naive Bayes by [Imran Haque](#).
- Added `partial_fit` to `BernoulliRBM` By [Danny Sullivan](#).
- Added `learning_curve` utility to chart performance with respect to training size. See *Plotting Learning Curves*. By [Alexander Fabisch](#).
- Add positive option in `LassoCV` and `ElasticNetCV`. By [Brian Wignall](#) and [Alexandre Gramfort](#).
- Added `linear_model.MultiTaskElasticNetCV` and `linear_model.MultiTaskLassoCV`. By [Manoj Kumar](#).
- Added `manifold.TSNE`. By [Alexander Fabisch](#).

### Enhancements

- Add sparse input support to `ensemble.AdaBoostClassifier` and `ensemble.AdaBoostRegressor` meta-estimators. By [Hamzeh Alsalhi](#).
- Memory improvements of decision trees, by [Arnaud Joly](#).
- Decision trees can now be built in best-first manner by using `max_leaf_nodes` as the stopping criteria. Refactored the tree code to use either a stack or a priority queue for tree building. By [Peter Prettenhofer](#) and [Gilles Louppe](#).
- Decision trees can now be fitted on fortran- and c-style arrays, and non-continuous arrays without the need to make a copy. If the input array has a different dtype than `np.float32`, a fortran- style copy will be made since fortran-style memory layout has speed advantages. By [Peter Prettenhofer](#) and [Gilles Louppe](#).
- Speed improvement of regression trees by optimizing the the computation of the mean square error criterion. This lead to speed improvement of the tree, forest and gradient boosting tree modules. By [Arnaud Joly](#)
- The `img_to_graph` and `grid_to_graph` functions in `sklearn.feature_extraction.image` now return `np.ndarray` instead of `np.matrix` when `return_as=np.ndarray`. See the Notes section for more information on compatibility.

- Changed the internal storage of decision trees to use a struct array. This fixed some small bugs, while improving code and providing a small speed gain. By [Joel Nothman](#).
- Reduce memory usage and overhead when fitting and predicting with forests of randomized trees in parallel with `n_jobs != 1` by leveraging new threading backend of joblib 0.8 and releasing the GIL in the tree fitting Cython code. By [Olivier Grisel](#) and [Gilles Louppe](#).
- Speed improvement of the `sklearn.ensemble.gradient_boosting` module. By [Gilles Louppe](#) and [Peter Prettenhofer](#).
- Various enhancements to the `sklearn.ensemble.gradient_boosting` module: a `warm_start` argument to fit additional trees, a `max_leaf_nodes` argument to fit GBM style trees, a `monitor` fit argument to inspect the estimator during training, and refactoring of the verbose code. By [Peter Prettenhofer](#).
- Faster `sklearn.ensemble.ExtraTrees` by caching feature values. By [Arnaud Joly](#).
- Faster depth-based tree building algorithm such as decision tree, random forest, extra trees or gradient tree boosting (with depth based growing strategy) by avoiding trying to split on found constant features in the sample subset. By [Arnaud Joly](#).
- Add `min_weight_fraction_leaf` pre-pruning parameter to tree-based methods: the minimum weighted fraction of the input samples required to be at a leaf node. By [Noel Dawe](#).
- Added `metrics.pairwise_distances_argmin_min`, by [Philippe Gervais](#).
- Added predict method to `cluster.AffinityPropagation` and `cluster.MeanShift`, by [Mathieu Blondel](#).
- Vector and matrix multiplications have been optimised throughout the library by [Denis Engemann](#), and [Alexandre Gramfort](#). In particular, they should take less memory with older NumPy versions (prior to 1.7.2).
- Precision-recall and ROC examples now use `train_test_split`, and have more explanation of why these metrics are useful. By [Kyle Kastner](#)
- The training algorithm for `decomposition.NMF` is faster for sparse matrices and has much lower memory complexity, meaning it will scale up gracefully to large datasets. By [Lars Buitinck](#).
- Added `svd_method` option with default value to “randomized” to `decomposition.FactorAnalysis` to save memory and significantly speedup computation by [Denis Engemann](#), and [Alexandre Gramfort](#).
- Changed `cross_validation.StratifiedKFold` to try and preserve as much of the original ordering of samples as possible so as not to hide overfitting on datasets with a non-negligible level of samples dependency. By [Daniel Nouri](#) and [Olivier Grisel](#).
- Add multi-output support to `gaussian_process.GaussianProcess` by [John Novak](#).
- Support for precomputed distance matrices in nearest neighbor estimators by [Robert Layton](#) and [Joel Nothman](#).
- Norm computations optimized for NumPy 1.6 and later versions by [Lars Buitinck](#). In particular, the k-means algorithm no longer needs a temporary data structure the size of its input.
- `dummy.DummyClassifier` can now be used to predict a constant output value. By [Manoj Kumar](#).
- `dummy.DummyRegressor` has now a strategy parameter which allows to predict the mean, the median of the training set or a constant output value. By [Maheshakya Wijewardena](#).
- Multi-label classification output in multilabel indicator format is now supported by `metrics.roc_auc_score` and `metrics.average_precision_score` by [Arnaud Joly](#).
- Significant performance improvements (more than 100x speedup for large problems) in `isotonic.IsotonicRegression` by [Andrew Tulloch](#).
- Speed and memory usage improvements to the SGD algorithm for linear models: it now uses threads, not separate processes, when `n_jobs>1`. By [Lars Buitinck](#).

- Grid search and cross validation allow NaNs in the input arrays so that preprocessors such as `preprocessing.Imputer` can be trained within the cross validation loop, avoiding potentially skewed results.
- Ridge regression can now deal with sample weights in feature space (only sample space until then). By Michael Eickenberg. Both solutions are provided by the Cholesky solver.
- Several classification and regression metrics now support weighted samples with the new `sample_weight` argument: `metrics.accuracy_score`, `metrics.zero_one_loss`, `metrics.precision_score`, `metrics.average_precision_score`, `metrics.f1_score`, `metrics.fbeta_score`, `metrics.recall_score`, `metrics.roc_auc_score`, `metrics.explained_variance_score`, `metrics.mean_squared_error`, `metrics.mean_absolute_error`, `metrics.r2_score`. By Noel Dawe.
- Speed up of the sample generator `datasets.make_multilabel_classification`. By Joel Nothman.

## Documentation improvements

- The `Working With Text Data` tutorial has now been worked in to the main documentation's tutorial section. Includes exercises and skeletons for tutorial presentation. Original tutorial created by several authors including Olivier Grisel, Lars Buitinck and many others. Tutorial integration into the scikit-learn documentation by Jaques Grobler
- Added `Computational Performance` documentation. Discussion and examples of prediction latency / throughput and different factors that have influence over speed. Additional tips for building faster models and choosing a relevant compromise between speed and predictive power. By Eustache Diemert.

## Bug fixes

- Fixed bug in `decomposition.MiniBatchDictionaryLearning`: `partial_fit` was not working properly.
- Fixed bug in `linear_model.stochastic_gradient`: `l1_ratio` was used as `(1.0 - l1_ratio)`.
- Fixed bug in `multiclass.OneVsOneClassifier` with string labels
- Fixed a bug in `LassoCV` and `ElasticNetCV`: they would not pre-compute the Gram matrix with `precompute=True` or `precompute="auto"` and `n_samples > n_features`. By Manoj Kumar.
- Fixed incorrect estimation of the degrees of freedom in `feature_selection.f_regression` when variates are not centered. By Virgile Fritsch.
- Fixed a race condition in parallel processing with `pre_dispatch != "all"` (for instance, in `cross_val_score`). By Olivier Grisel.
- Raise error in `cluster.FeatureAgglomeration` and `cluster.WardAgglomeration` when no samples are given, rather than returning meaningless clustering.
- Fixed bug in `gradient_boosting.GradientBoostingRegressor` with `loss='huber'`: gamma might have not been initialized.
- Fixed feature importances as computed with a forest of randomized trees when fit with `sample_weight != None` and/or with `bootstrap=True`. By Gilles Louppe.

## API changes summary

- `sklearn.hmm` is deprecated. Its removal is planned for the 0.17 release.
- Use of `covariance.EllipticEnvelop` has now been removed after deprecation. Please use `covariance.EllipticEnvelope` instead.
- `cluster.Ward` is deprecated. Use `cluster.AgglomerativeClustering` instead.
- `cluster.WardClustering` is deprecated. Use  
`cluster.AgglomerativeClustering` instead.
- `cross_validation.Bootstrap` is deprecated. `cross_validation.KFold` or  
`cross_validation.ShuffleSplit` are recommended instead.
- Direct support for the sequence of sequences (or list of lists) multilabel format is deprecated. To convert to and from the supported binary indicator matrix format, use `MultiLabelBinarizer`. By [Joel Nothman](#).
- Add score method to `PCA` following the model of probabilistic PCA and deprecate `ProbabilisticPCA` model whose score implementation is not correct. The computation now also exploits the matrix inversion lemma for faster computation. By [Alexandre Gramfort](#).
- The score method of `FactorAnalysis` now returns the average log-likelihood of the samples. Use `score_samples` to get log-likelihood of each sample. By [Alexandre Gramfort](#).
- Generating boolean masks (the setting `indices=False`) from cross-validation generators is deprecated. Support for masks will be removed in 0.17. The generators have produced arrays of indices by default since 0.10. By [Joel Nothman](#).
- 1-d arrays containing strings with `dtype=object` (as used in Pandas) are now considered valid classification targets. This fixes a regression from version 0.13 in some classifiers. By [Joel Nothman](#).
- Fix wrong `explained_variance_ratio_` attribute in `RandomizedPCA`. By [Alexandre Gramfort](#).
- Fit alphas for each `l1_ratio` instead of `mean_l1_ratio` in `linear_model.ElasticNetCV` and `linear_model.LassoCV`. This changes the shape of `alphas_` from `(n_alphas,)` to `(n_l1_ratio, n_alphas)` if the `l1_ratio` provided is a 1-D array like object of length greater than one. By [Manoj Kumar](#).
- Fix `linear_model.ElasticNetCV` and `linear_model.LassoCV` when fitting intercept and input data is sparse. The automatic grid of alphas was not computed correctly and the scaling with normalize was wrong. By [Manoj Kumar](#).
- Fix wrong maximal number of features drawn (`max_features`) at each split for decision trees, random forests and gradient tree boosting. Previously, the count for the number of drawn features started only after one non constant features in the split. This bug fix will affect computational and generalization performance of those algorithms in the presence of constant features. To get back previous generalization performance, you should modify the value of `max_features`. By [Arnaud Joly](#).
- Fix wrong maximal number of features drawn (`max_features`) at each split for `ensemble.ExtraTreesClassifier` and `ensemble.ExtraTreesRegressor`. Previously, only non constant features in the split was counted as drawn. Now constant features are counted as drawn. Furthermore at least one feature must be non constant in order to make a valid split. This bug fix will affect computational and generalization performance of extra trees in the presence of constant features. To get back previous generalization performance, you should modify the value of `max_features`. By [Arnaud Joly](#).
- Fix `utils.compute_class_weight` when `class_weight=="auto"`. Previously it was broken for input of non-integer `dtype` and the weighted array that was returned was wrong. By [Manoj Kumar](#).
- Fix `cross_validation.Bootstrap` to return `ValueError` when `n_train + n_test > n`. By [Ronald Phlypo](#).

### 1.7.11 Version 0.14

August 7, 2013

#### Changelog

- Missing values with sparse and dense matrices can be imputed with the transformer `preprocessing.Imputer` by Nicolas Trésegnyie.
- The core implementation of decisions trees has been rewritten from scratch, allowing for faster tree induction and lower memory consumption in all tree-based estimators. By Gilles Louppe.
- Added `ensemble.AdaBoostClassifier` and `ensemble.AdaBoostRegressor`, by Noel Dawe and Gilles Louppe. See the `AdaBoost` section of the user guide for details and examples.
- Added `grid_search.RandomizedSearchCV` and `grid_search.ParameterSampler` for randomized hyperparameter optimization. By Andreas Müller.
- Added `biclustering` algorithms (`sklearn.cluster.bicluster.SpectralCoclustering` and `sklearn.cluster.bicluster.SpectralBiclustering`), data generation methods (`sklearn.datasets.make_biclusters` and `sklearn.datasets.make_checkerboard`), and scoring metrics (`sklearn.metrics.consensus_score`). By Kemal Eren.
- Added *Restricted Boltzmann Machines* (`neural_network.BernoulliRBM`). By Yann Dauphin.

- Python 3 support by [Justin Vincent](#), [Lars Buitinck](#), [Subhodeep Moitra](#) and [Olivier Grisel](#). All tests now pass under Python 3.3.
- Ability to pass one penalty (alpha value) per target in `linear_model.Ridge`, by [@eickenberg](#) and [Mathieu Blondel](#).
- Fixed `sklearn.linear_model.stochastic_gradient.py` L2 regularization issue (minor practical significance). By [Norbert Crombach](#) and [Mathieu Blondel](#).
- Added an interactive version of [Andreas Müller's Machine Learning Cheat Sheet](#) (for scikit-learn) to the documentation. See [Choosing the right estimator](#). By [Jaques Grobler](#).
- `grid_search.GridSearchCV` and `cross_validation.cross_val_score` now support the use of advanced scoring function such as area under the ROC curve and f-beta scores. See [The scoring parameter: defining model evaluation rules](#) for details. By [Andreas Müller](#) and [Lars Buitinck](#). Passing a function from `sklearn.metrics` as `score_func` is deprecated.
- Multi-label classification output is now supported by `metrics.accuracy_score`, `metrics.zero_one_loss`, `metrics.f1_score`, `metrics.fbeta_score`, `metrics.classification_report`, `metrics.precision_score` and `metrics.recall_score` by [Arnaud Joly](#).
- Two new metrics `metrics.hamming_loss` and `metrics.jaccard_similarity_score` are added with multi-label support by [Arnaud Joly](#).
- Speed and memory usage improvements in `feature_extraction.text.CountVectorizer` and `feature_extraction.text.TfidfVectorizer`, by [Jochen Wersdörfer](#) and [Roman Sinayev](#).
- The `min_df` parameter in `feature_extraction.text.CountVectorizer` and `feature_extraction.text.TfidfVectorizer`, which used to be 2, has been reset to 1 to avoid unpleasant surprises (empty vocabularies) for novice users who try it out on tiny document collections. A value of at least 2 is still recommended for practical use.
- `svm.LinearSVC`, `linear_model.SGDClassifier` and `linear_model.SGDRegressor` now have a `sparsify` method that converts their `coef_` into a sparse matrix, meaning stored models trained using these estimators can be made much more compact.
- `linear_model.SGDClassifier` now produces multiclass probability estimates when trained under log loss or modified Huber loss.
- Hyperlinks to documentation in example code on the website by [Martin Luessi](#).
- Fixed bug in `preprocessing.MinMaxScaler` causing incorrect scaling of the features for non-default `feature_range` settings. By [Andreas Müller](#).
- `max_features` in `tree.DecisionTreeClassifier`, `tree.DecisionTreeRegressor` and all derived ensemble estimators now supports percentage values. By [Gilles Louppe](#).
- Performance improvements in `isotonic.IsotonicRegression` by [Nelle Varoquaux](#).
- `metrics.accuracy_score` has an option `normalize` to return the fraction or the number of correctly classified sample by [Arnaud Joly](#).
- Added `metrics.log_loss` that computes log loss, aka cross-entropy loss. By [Jochen Wersdörfer](#) and [Lars Buitinck](#).
- A bug that caused `ensemble.AdaBoostClassifier`'s to output incorrect probabilities has been fixed.
- Feature selectors now share a mixin providing consistent `transform`, `inverse_transform` and `get_support` methods. By [Joel Nothman](#).
- A fitted `grid_search.GridSearchCV` or `grid_search.RandomizedSearchCV` can now generally be pickled. By [Joel Nothman](#).

- Refactored and vectorized implementation of `metrics.roc_curve` and `metrics.precision_recall_curve`. By [Joel Nothman](#).
- The new estimator `sklearn.decomposition.TruncatedSVD` performs dimensionality reduction using SVD on sparse matrices, and can be used for latent semantic analysis (LSA). By [Lars Buitinck](#).
- Added self-contained example of out-of-core learning on text data *Out-of-core classification of text documents*. By [Eustache Diemert](#).
- The default number of components for `sklearn.decomposition.RandomizedPCA` is now correctly documented to be `n_features`. This was the default behavior, so programs using it will continue to work as they did.
- `sklearn.cluster.KMeans` now fits several orders of magnitude faster on sparse data (the speedup depends on the sparsity). By [Lars Buitinck](#).
- Reduce memory footprint of FastICA by [Denis Engemann](#) and [Alexandre Gramfort](#).
- Verbose output in `sklearn.ensemble.gradient_boosting` now uses a column format and prints progress in decreasing frequency. It also shows the remaining time. By [Peter Prettenhofer](#).
- `sklearn.ensemble.gradient_boosting` provides out-of-bag improvement `oob_improvement_` rather than the OOB score for model selection. An example that shows how to use OOB estimates to select the number of trees was added. By [Peter Prettenhofer](#).
- Most metrics now support string labels for multiclass classification by [Arnaud Joly](#) and [Lars Buitinck](#).
- New `OrthogonalMatchingPursuitCV` class by [Alexandre Gramfort](#) and [Vlad Niculae](#).
- Fixed a bug in `sklearn.covariance.GraphLassoCV`: the ‘alphas’ parameter now works as expected when given a list of values. By [Philippe Gervais](#).
- Fixed an important bug in `sklearn.covariance.GraphLassoCV` that prevented all folds provided by a CV object to be used (only the first 3 were used). When providing a CV object, execution time may thus increase significantly compared to the previous version (bug results are correct now). By [Philippe Gervais](#).
- `cross_validation.cross_val_score` and the `grid_search` module is now tested with multi-output data by [Arnaud Joly](#).
- `datasets.make_multilabel_classification` can now return the output in label indicator multilabel format by [Arnaud Joly](#).
- K-nearest neighbors, `neighbors.KNeighborsRegressor` and `neighbors.RadiusNeighborsRegressor`, and radius neighbors, `neighbors.RadiusNeighborsClassifier` support multioutput data by [Arnaud Joly](#).
- Random state in LibSVM-based estimators (`svm.SVC`, `NuSVC`, `OneClassSVM`, `svm.SVR`, `svm.NuSVR`) can now be controlled. This is useful to ensure consistency in the probability estimates for the classifiers trained with `probability=True`. By [Vlad Niculae](#).
- Out-of-core learning support for discrete naive Bayes classifiers `sklearn.naive_bayes.MultinomialNB` and `sklearn.naive_bayes.BernoulliNB` by adding the `partial_fit` method by [Olivier Grisel](#).
- New website design and navigation by [Gilles Louppe](#), [Nelle Varoquaux](#), [Vincent Michel](#) and [Andreas Müller](#).
- Improved documentation on *multi-class, multi-label and multi-output classification* by [Yannick Schwartz](#) and [Arnaud Joly](#).
- Better input and error handling in the `metrics` module by [Arnaud Joly](#) and [Joel Nothman](#).
- Speed optimization of the `hmm` module by [Mikhail Korobov](#)
- Significant speed improvements for `sklearn.cluster.DBSCAN` by [cleverless](#)

## API changes summary

- The `auc_score` was renamed `roc_auc_score`.
- Testing scikit-learn with `sklearn.test()` is deprecated. Use `nosetests sklearn` from the command line.
- Feature importances in `tree.DecisionTreeClassifier`, `tree.DecisionTreeRegressor` and all derived ensemble estimators are now computed on the fly when accessing the `feature_importances_` attribute. Setting `compute_importances=True` is no longer required. By [Gilles Louppe](#).
- `linear_model.lasso_path` and `linear_model.enet_path` can return its results in the same format as that of `linear_model.lars_path`. This is done by setting the `return_models` parameter to `False`. By [Jaques Grobler](#) and [Alexandre Gramfort](#)
- `grid_search.IterGrid` was renamed to `grid_search.ParameterGrid`.
- Fixed bug in `KFold` causing imperfect class balance in some cases. By [Alexandre Gramfort](#) and [Tadej Janež](#).
- `sklearn.neighbors.BallTree` has been refactored, and a `sklearn.neighbors.KDTree` has been added which shares the same interface. The Ball Tree now works with a wide variety of distance metrics. Both classes have many new methods, including single-tree and dual-tree queries, breadth-first and depth-first searching, and more advanced queries such as kernel density estimation and 2-point correlation functions. By [Jake Vanderplas](#)
- Support for `scipy.spatial.cKDTree` within `neighbors` queries has been removed, and the functionality replaced with the new `KDTree` class.
- `sklearn.neighbors.KernelDensity` has been added, which performs efficient kernel density estimation with a variety of kernels.
- `sklearn.decomposition.KernelPCA` now always returns output with `n_components` components, unless the new parameter `remove_zero_eig` is set to `True`. This new behavior is consistent with the way kernel PCA was always documented; previously, the removal of components with zero eigenvalues was tacitly performed on all data.
- `gcv_mode="auto"` no longer tries to perform SVD on a densified sparse matrix in `sklearn.linear_model.RidgeCV`.
- Sparse matrix support in `sklearn.decomposition.RandomizedPCA` is now deprecated in favor of the new `TruncatedSVD`.
- `cross_validation.KFold` and `cross_validation.StratifiedKFold` now enforce `n_folds >= 2` otherwise a `ValueError` is raised. By [Olivier Grisel](#).
- `datasets.load_files`'s `charset` and `charset_errors` parameters were renamed `encoding` and `decode_errors`.
- Attribute `oob_score_` in `sklearn.ensemble.GradientBoostingRegressor` and `sklearn.ensemble.GradientBoostingClassifier` is deprecated and has been replaced by `oob_improvement_`.
- Attributes in `OrthogonalMatchingPursuit` have been deprecated (`copy_X`, `Gram`, ...) and `precompute_gram` renamed `precompute` for consistency. See #2224.
- `sklearn.preprocessing.StandardScaler` now converts integer input to float, and raises a warning. Previously it rounded for dense integer input.
- `sklearn.multiclass.OneVsRestClassifier` now has a `decision_function` method. This will return the distance of each sample from the decision boundary for each class, as long as the underlying estimators implement the `decision_function` method. By [Kyle Kastner](#).
- Better input validation, warning on unexpected shapes for `y`.

## 1.7.12 Version 0.13.1

February 23, 2013

The 0.13.1 release only fixes some bugs and does not add any new functionality.

### Changelog

- Fixed a testing error caused by the function `cross_validation.train_test_split` being interpreted as a test by [Yaroslav Halchenko](#).
- Fixed a bug in the reassignment of small clusters in the `cluster.MiniBatchKMeans` by [Gael Varoquaux](#).
- Fixed default value of `gamma` in `decomposition.KernelPCA` by [Lars Buitinck](#).
- Updated joblib to 0.7.0d by [Gael Varoquaux](#).
- Fixed scaling of the deviance in `ensemble.GradientBoostingClassifier` by [Peter Prettenhofer](#).
- Better tie-breaking in `multiclass.OneVsOneClassifier` by [Andreas Müller](#).
- Other small improvements to tests and documentation.

### 1.7.13 Version 0.13

January 21, 2013

#### New Estimator Classes

- `dummy.DummyClassifier` and `dummy.DummyRegressor`, two data-independent predictors by Mathieu Blondel. Useful to sanity-check your estimators. See [Dummy estimators](#) in the user guide. Multioutput support added by Arnaud Joly.
- `decomposition.FactorAnalysis`, a transformer implementing the classical factor analysis, by Christian Osendorfer and Alexandre Gramfort. See [Factor Analysis](#) in the user guide.
- `feature_extraction.FeatureHasher`, a transformer implementing the “hashing trick” for fast, low-memory feature extraction from string fields by Lars Buitinck and `feature_extraction.text.HashingVectorizer` for text documents by Olivier Grisel. See [Feature hashing](#) and [Vectorizing a large text corpus with the hashing trick](#) for the documentation and sample usage.
- `pipeline.FeatureUnion`, a transformer that concatenates results of several other transformers by Andreas Müller. See [FeatureUnion: composite feature spaces](#) in the user guide.
- `random_projection.GaussianRandomProjection`, `SparseRandomProjection` and the function `random_projection.johnson_lindenstrauss_min_dim`. The first two are transformers implementing Gaussian and sparse random projection matrix by Olivier Grisel and Arnaud Joly. See [Random Projection](#) in the user guide.
- `kernel_approximation.Nystroem`, a transformer for approximating arbitrary kernels by Andreas Müller. See [Nystroem Method for Kernel Approximation](#) in the user guide.

- `preprocessing.OneHotEncoder`, a transformer that computes binary encodings of categorical features by Andreas Müller. See [Encoding categorical features](#) in the user guide.
- `linear_model.PассивагрессивныйКлассификатор` и `linear_model.PассивагрессивныйРегрессор`, предикторы, реализующие эффективную стохастическую оптимизацию для линейных моделей by Rob Zinkov и Mathieu Blondel. See [Passive Aggressive Algorithms](#) в пользовательском руководстве.
- `ensemble.RandomTreesEmbedding`, трансформер для создания высокодimensionalных разреженных представлений с помощью ансамблей полностью случайных деревьев by Andreas Müller. See [Totally Random Trees Embedding](#) в пользовательском руководстве.
- `manifold.SpectralEmbedding` и функция `manifold.spectral_embedding`, реализующие трансформацию «лапласианских собственных значений» для нелинейного снижения размерности by Wei Li. See [Spectral Embedding](#) в пользовательском руководстве.
- `isotonic.IsotonicRegression` by Fabian Pedregosa, Alexandre Gramfort и Nelle Varoquaux,

## Changelog

- `metrics.zero_one_loss` (ранее `metrics.zero_one`) теперь имеет опцию для нормализованного выхода, который отчитывает долю ошибочных классификаций, а не количество ошибочных классификаций. By Kyle Beauchamp.
- `tree.DecisionTreeClassifier` и все derived ensemble models now support sample weighting, by Noel Dawe и Gilles Louppe.
- Speedup improvement when using bootstrap samples in forests of randomized trees, by Peter Prettenhofer и Gilles Louppe.
- Partial dependence plots for *Gradient Tree Boosting* in `ensemble.partial_dependence.partial_dependence` by Peter Prettenhofer. See [Partial Dependence Plots](#) for an example.
- The table of contents on the website has now been made expandable by Jaques Grobler.
- `feature_selection.SelectPercentile` now breaks ties deterministically instead of returning all equally ranked features.
- `feature_selection.SelectKBest` и `feature_selection.SelectPercentile` more numerically stable since they use scores, rather than p-values, to rank results. This means that they might sometimes select different features than they did previously.
- Ridge regression and ridge classification fitting with `sparse_cg` solver no longer has quadratic memory complexity, by Lars Buitinck и Fabian Pedregosa.
- Ridge regression and ridge classification now support a new fast solver called `lsqr`, by Mathieu Blondel.
- Speed up of `metrics.precision_recall_curve` by Conrad Lee.
- Added support for reading/writing svmlight files with pairwise preference attribute (qid in svmlight file format) in `datasets.dump_svmlight_file` и `datasets.load_svmlight_file` by Fabian Pedregosa.
- Faster and more robust `metrics.confusion_matrix` и [Clustering performance evaluation](#) by Wei Li.
- `cross_validation.cross_val_score` now works with precomputed kernels and affinity matrices, by Andreas Müller.
- LARS algorithm made more numerically stable with heuristics to drop regressors too correlated as well as to stop the path when numerical noise becomes predominant, by Gael Varoquaux.
- Faster implementation of `metrics.precision_recall_curve` by Conrad Lee.
- New kernel `metrics.chi2_kernel` by Andreas Müller, often used in computer vision applications.
- Fix of longstanding bug in `naive_bayes.BernoulliNB` fixed by Shaun Jackman.

- Implemented `predict_proba` in `multiclass.OneVsRestClassifier`, by Andrew Winterman.
- Improve consistency in gradient boosting: estimators `ensemble.GradientBoostingRegressor` and `ensemble.GradientBoostingClassifier` use the estimator `tree.DecisionTreeRegressor` instead of the `tree._tree.Tree` data structure by Arnaud Joly.
- Fixed a floating point exception in the `decision trees` module, by Seberg.
- Fix `metrics.roc_curve` fails when `y_true` has only one class by Wei Li.
- Add the `metrics.mean_absolute_error` function which computes the mean absolute error. The `metrics.mean_squared_error`, `metrics.mean_absolute_error` and `metrics.r2_score` metrics support multioutput by Arnaud Joly.
- Fixed `class_weight` support in `svm.LinearSVC` and `linear_model.LogisticRegression` by Andreas Müller. The meaning of `class_weight` was reversed as erroneously higher weight meant less positives of a given class in earlier releases.
- Improve narrative documentation and consistency in `sklearn.metrics` for regression and classification metrics by Arnaud Joly.
- Fixed a bug in `sklearn.svm.SVC` when using csr-matrices with unsorted indices by Xinfan Meng and Andreas Müller.
- MiniBatchKMeans: Add random reassignment of cluster centers with little observations attached to them, by Gael Varoquaux.

## API changes summary

- Renamed all occurrences of `n_atoms` to `n_components` for consistency. This applies to `decomposition.DictionaryLearning`, `MiniBatchDictionaryLearning`, `decomposition.dict_learning`, `decomposition.dict_learning_online`.
- Renamed all occurrences of `max_iters` to `max_iter` for consistency. This applies to `semi_supervised.LabelPropagation` and `semi_supervised.label_propagation.LabelSpreading`.
- Renamed all occurrences of `learn_rate` to `learning_rate` for consistency in `ensemble.BaseGradientBoosting` and `ensemble.GradientBoostingRegressor`.
- The module `sklearn.linear_model.sparse` is gone. Sparse matrix support was already integrated into the “regular” linear models.
- `sklearn.metrics.mean_square_error`, which incorrectly returned the accumulated error, was removed. Use `mean_squared_error` instead.
- Passing `class_weight` parameters to `fit` methods is no longer supported. Pass them to estimator constructors instead.
- GMMs no longer have `decode` and `rvs` methods. Use the `score`, `predict` or `sample` methods instead.
- The `solver` fit option in Ridge regression and classification is now deprecated and will be removed in v0.14. Use the constructor option instead.
- `feature_extraction.text.DictVectorizer` now returns sparse matrices in the CSR format, instead of COO.
- Renamed `k` in `cross_validation.KFold` and `cross_validation.StratifiedKFold` to `n_folds`, renamed `n_bootstraps` to `n_iter` in `cross_validation.Bootstrap`.

- Renamed all occurrences of `n_iterations` to `n_iter` for consistency. This applies to `cross_validation.ShuffleSplit`, `cross_validation.StratifiedShuffleSplit`, `utils.randomized_range_finder` and `utils.randomized_svd`.
- Replaced `rho` in `linear_model.ElasticNet` and `linear_model.SGDClassifier` by `l1_ratio`. The `rho` parameter had different meanings; `l1_ratio` was introduced to avoid confusion. It has the same meaning as previously `rho` in `linear_model.ElasticNet` and `(1-rho)` in `linear_model.SGDClassifier`.
- `linear_model.LassoLars` and `linear_model.Lars` now store a list of paths in the case of multiple targets, rather than an array of paths.
- The attribute `gmm` of `hmm.GMMHMM` was renamed to `gmm_` to adhere more strictly with the API.
- `cluster.spectral_embedding` was moved to `manifold.spectral_embedding`.
- Renamed `eig_tol` in `manifold.spectral_embedding`, `cluster.SpectralClustering` to `eigen_tol`, renamed mode to `eigen_solver`.
- Renamed mode in `manifold.spectral_embedding` and `cluster.SpectralClustering` to `eigen_solver`.
- `classes_` and `n_classes_` attributes of `tree.DecisionTreeClassifier` and all derived ensemble models are now flat in case of single output problems and nested in case of multi-output problems.
- The `estimators_` attribute of `ensemble.gradient_boosting.GradientBoostingRegressor` and `ensemble.gradient_boosting.GradientBoostingClassifier` is now an array of `:class:`tree.DecisionTreeRegressor``.
- Renamed `chunk_size` to `batch_size` in `decomposition.MiniBatchDictionaryLearning` and `decomposition.MiniBatchSparsePCA` for consistency.
- `svm.SVC` and `svm.NuSVC` now provide a `classes_` attribute and support arbitrary dtypes for labels `y`. Also, the `dtype` returned by `predict` now reflects the `dtype` of `y` during `fit` (used to be `np.float`).
- Changed default `test_size` in `cross_validation.train_test_split` to `None`, added possibility to infer `test_size` from `train_size` in `cross_validation.ShuffleSplit` and `cross_validation.StratifiedShuffleSplit`.
- Renamed function `sklearn.metrics.zero_one` to `sklearn.metrics.zero_one_loss`. Be aware that the default behavior in `sklearn.metrics.zero_one_loss` is different from `sklearn.metrics.zero_one`: `normalize=False` is changed to `normalize=True`.
- Renamed function `metrics.zero_one_score` to `metrics.accuracy_score`.
- `datasets.make_circles` now has the same number of inner and outer points.
- In the Naive Bayes classifiers, the `class_prior` parameter was moved from `fit` to `__init__`.

### 1.7.14 Version 0.12.1

**October 8, 2012**

The 0.12.1 release is a bug-fix release with no additional features, but is instead a set of bug fixes

#### Changelog

- Improved numerical stability in spectral embedding by [Gael Varoquaux](#)
- Doctest under windows 64bit by [Gael Varoquaux](#)
- Documentation fixes for elastic net by [Andreas Müller](#) and [Alexandre Gramfort](#)
- Proper behavior with fortran-ordered NumPy arrays by [Gael Varoquaux](#)
- Make GridSearchCV work with non-CSR sparse matrix by [Lars Buitinck](#)
- Fix parallel computing in MDS by [Gael Varoquaux](#)

- Fix Unicode support in count vectorizer by [Andreas Müller](#)
- Fix MinCovDet breaking with  $X.shape = (3, 1)$  by [Virgile Fritsch](#)
- Fix clone of SGD objects by [Peter Prettenhofer](#)
- Stabilize GMM by [Virgile Fritsch](#)

## People

- 14 [Peter Prettenhofer](#)
- 12 [Gael Varoquaux](#)
- 10 [Andreas Müller](#)

## 1.7.15 Version 0.12

September 4, 2012

### Changelog

- Various speed improvements of the [\*decision trees\*](#) module, by [Gilles Louppe](#).
- [\*ensemble.GradientBoostingRegressor\*](#) and [\*ensemble.GradientBoostingClassifier\*](#) now support feature subsampling via the `max_features` argument, by [Peter Prettenhofer](#).
- Added Huber and Quantile loss functions to [\*ensemble.GradientBoostingRegressor\*](#), by [Peter Prettenhofer](#).
- [\*Decision trees\*](#) and [\*forests of randomized trees\*](#) now support multi-output classification and regression problems, by [Gilles Louppe](#).
- Added [\*preprocessing.LabelEncoder\*](#), a simple utility class to normalize labels or transform non-numerical labels, by [Mathieu Blondel](#).
- Added the epsilon-insensitive loss and the ability to make probabilistic predictions with the modified huber loss in [\*Stochastic Gradient Descent\*](#), by [Mathieu Blondel](#).
- Added [\*Multi-dimensional Scaling \(MDS\)\*](#), by [Nelle Varoquaux](#).
- SVMlight file format loader now detects compressed (gzip/bzip2) files and decompresses them on the fly, by [Lars Buitinck](#).
- SVMlight file format serializer now preserves double precision floating point values, by [Olivier Grisel](#).
- A common testing framework for all estimators was added, by [Andreas Müller](#).
- Understandable error messages for estimators that do not accept sparse input by [Gael Varoquaux](#)
- Speedups in hierarchical clustering by [Gael Varoquaux](#). In particular building the tree now supports early stopping. This is useful when the number of clusters is not small compared to the number of samples.

- Add MultiTaskLasso and MultiTaskElasticNet for joint feature selection, by [Alexandre Gramfort](#).
- Added `metrics.auc_score` and `metrics.average_precision_score` convenience functions by [Andreas Müller](#).
- Improved sparse matrix support in the [Feature selection](#) module by [Andreas Müller](#).
- New word boundaries-aware character n-gram analyzer for the [Text feature extraction](#) module by [@kernc](#).
- Fixed bug in spectral clustering that led to single point clusters by [Andreas Müller](#).
- In `feature_extraction.text.CountVectorizer`, added an option to ignore infrequent words, `min_df` by [Andreas Müller](#).
- Add support for multiple targets in some linear models (ElasticNet, Lasso and OrthogonalMatchingPursuit) by [Vlad Niculae](#) and [Alexandre Gramfort](#).
- Fixes in `decomposition.ProbabilisticPCA` score function by [Wei Li](#).
- Fixed feature importance computation in [Gradient Tree Boosting](#).

## API changes summary

- The old `scikits.learn` package has disappeared; all code should import from `sklearn` instead, which was introduced in 0.9.
- In `metrics.roc_curve`, the `thresholds` array is now returned with its order reversed, in order to keep it consistent with the order of the returned `fpr` and `tpr`.
- In `hmm` objects, like `hmm.GaussianHMM`, `hmm.MultinomialHMM`, etc., all parameters must be passed to the object when initialising it and not through `fit`. Now `fit` will only accept the data as an input parameter.
- For all SVM classes, a faulty behavior of `gamma` was fixed. Previously, the default `gamma` value was only computed the first time `fit` was called and then stored. It is now recalculated on every call to `fit`.
- All `Base` classes are now abstract meta classes so that they can not be instantiated.
- `cluster.ward_tree` now also returns the parent array. This is necessary for early-stopping in which case the tree is not completely built.
- In `feature_extraction.text.CountVectorizer` the parameters `min_n` and `max_n` were joined to the parameter `n_gram_range` to enable grid-searching both at once.
- In `feature_extraction.text.CountVectorizer`, words that appear only in one document are now ignored by default. To reproduce the previous behavior, set `min_df=1`.
- Fixed API inconsistency: `linear_model.SGDClassifier.predict_proba` now returns 2d array when fit on two classes.
- Fixed API inconsistency: `discriminant_analysis.QuadraticDiscriminantAnalysis.decision_function` and `discriminant_analysis.LinearDiscriminantAnalysis.decision_function` now return 1d arrays when fit on two classes.
- Grid of alphas used for fitting `linear_model.LassoCV` and `linear_model.ElasticNetCV` is now stored in the attribute `alphas_` rather than overriding the init parameter `alphas`.
- Linear models when alpha is estimated by cross-validation store the estimated value in the `alpha_` attribute rather than just `alpha` or `best_alpha`.
- `ensemble.GradientBoostingClassifier` now supports `GradientBoostingClassifier.staged_predict_proba`, and `GradientBoostingClassifier.staged_predict`.

- `svm.sparse.SVC` and other sparse SVM classes are now deprecated. The all classes in the *Support Vector Machines* module now automatically select the sparse or dense representation base on the input.
- All clustering algorithms now interpret the array `X` given to `fit` as input data, in particular `cluster.SpectralClustering` and `cluster.AffinityPropagation` which previously expected affinity matrices.
- For clustering algorithms that take the desired number of clusters as a parameter, this parameter is now called `n_clusters`.

## 1.7.16 Version 0.11

May 7, 2012

### Changelog

### Highlights

- Gradient boosted regression trees (*Gradient Tree Boosting*) for classification and regression by [Peter Prettenhofer](#) and [Scott White](#).
- Simple dict-based feature loader with support for categorical variables (*feature\_extraction.DictVectorizer*) by [Lars Buitinck](#).
- Added Matthews correlation coefficient (*metrics.matthews\_corrcoef*) and added macro and micro average options to *metrics.precision\_score*, *metrics.recall\_score* and *metrics.f1\_score* by [Satrajit Ghosh](#).
- *Out of Bag Estimates* of generalization error for *Ensemble methods* by [Andreas Müller](#).
- *Randomized sparse models*: Randomized sparse linear models for feature selection, by [Alexandre Gramfort](#) and [Gael Varoquaux](#)
- *Label Propagation* for semi-supervised learning, by [Clay Woolam](#). **Note** the semi-supervised API is still work in progress, and may change.

- Added BIC/AIC model selection to classical *Gaussian mixture models* and unified the API with the remainder of scikit-learn, by Bertrand Thirion
- Added `sklearn.cross_validation.StratifiedShuffleSplit`, which is a `sklearn.cross_validation.ShuffleSplit` with balanced splits, by Yannick Schwartz.
- `sklearn.neighbors.NearestCentroid` classifier added, along with a `shrink_threshold` parameter, which implements **shrunken centroid classification**, by Robert Layton.

## Other changes

- Merged dense and sparse implementations of *Stochastic Gradient Descent* module and exposed utility extension types for sequential datasets `seq_dataset` and weight vectors `weight_vector` by Peter Prettenhofer.
- Added `partial_fit` (support for online/minibatch learning) and `warm_start` to the *Stochastic Gradient Descent* module by Mathieu Blondel.
- Dense and sparse implementations of *Support Vector Machines* classes and `linear_model.LogisticRegression` merged by Lars Buitinck.
- Regressors can now be used as base estimator in the *Multiclass and multilabel algorithms* module by Mathieu Blondel.
- Added `n_jobs` option to `metrics.pairwise.pairwise_distances` and `metrics.pairwise.pairwise_kernels` for parallel computation, by Mathieu Blondel.
- *K-means* can now be run in parallel, using the `n_jobs` argument to either *K-means* or KMeans, by Robert Layton.
- Improved *Cross-validation: evaluating estimator performance* and *Tuning the hyper-parameters of an estimator* documentation and introduced the new `cross_validation.train_test_split` helper function by Olivier Grisel
- `svm.SVC` members `coef_` and `intercept_` changed sign for consistency with `decision_function`; for `kernel==linear`, `coef_` was fixed in the one-vs-one case, by Andreas Müller.
- Performance improvements to efficient leave-one-out cross-validated Ridge regression, esp. for the `n_samples > n_features` case, in `linear_model.RidgeCV`, by Reuben Fletcher-Costin.
- Refactoring and simplification of the *Text feature extraction* API and fixed a bug that caused possible negative IDF, by Olivier Grisel.
- Beam pruning option in `_BaseHMM` module has been removed since it is difficult to Cythonize. If you are interested in contributing a Cython version, you can use the python version in the git history as a reference.
- Classes in *Nearest Neighbors* now support arbitrary Minkowski metric for nearest neighbors searches. The metric can be specified by argument `p`.

## API changes summary

- `covariance.EllipticEnvelop` is now deprecated - Please use `covariance.EllipticEnvelope` instead.
- `NeighborsClassifier` and `NeighborsRegressor` are gone in the module *Nearest Neighbors*. Use the classes `KNeighborsClassifier`, `RadiusNeighborsClassifier`, `KNeighborsRegressor` and/or `RadiusNeighborsRegressor` instead.
- Sparse classes in the *Stochastic Gradient Descent* module are now deprecated.

- In `mixture.GMM`, `mixture.DPGMM` and `mixture.VBGMM`, parameters must be passed to an object when initialising it and not through `fit`. Now `fit` will only accept the data as an input parameter.
- methods `rvs` and `decode` in GMM module are now deprecated. `sample` and `score` or `predict` should be used instead.
- attribute `_scores` and `_pvalues` in univariate feature selection objects are now deprecated. `scores_` or `pvalues_` should be used instead.
- In `LogisticRegression`, `LinearSVC`, `SVC` and `NuSVC`, the `class_weight` parameter is now an initialization parameter, not a parameter to fit. This makes grid searches over this parameter possible.
- LFW data is now always shape (`n_samples`, `n_features`) to be consistent with the Olivetti faces dataset. Use `images` and `pairs` attribute to access the natural images shapes instead.
- In `svm.LinearSVC`, the meaning of the `multi_class` parameter changed. Options now are '`ovr`' and '`crammer_singer`', with '`ovr`' being the default. This does not change the default behavior but hopefully is less confusing.
- Class `feature_selection.text.Vectorizer` is deprecated and replaced by `feature_selection.text.TfidfVectorizer`.
- The preprocessor / analyzer nested structure for text feature extraction has been removed. All those features are now directly passed as flat constructor arguments to `feature_selection.text.TfidfVectorizer` and `feature_selection.text.CountVectorizer`, in particular the following parameters are now used:
  - `analyzer` can be '`word`' or '`char`' to switch the default analysis scheme, or use a specific python callable (as previously).
  - `tokenizer` and `preprocessor` have been introduced to make it still possible to customize those steps with the new API.
  - `input` explicitly control how to interpret the sequence passed to `fit` and `predict`: filenames, file objects or direct (byte or Unicode) strings.
  - `charset` decoding is explicit and strict by default.
  - the `vocabulary`, fitted or not is now stored in the `vocabulary_` attribute to be consistent with the project conventions.
- Class `feature_selection.text.TfidfVectorizer` now derives directly from `feature_selection.text.CountVectorizer` to make grid search trivial.
- methods `rvs` in `_BaseHMM` module are now deprecated. `sample` should be used instead.
- Beam pruning option in `_BaseHMM` module is removed since it is difficult to be Cythonized. If you are interested, you can look in the history codes by git.
- The SVMlight format loader now supports files with both zero-based and one-based column indices, since both occur “in the wild”.
- Arguments in class `ShuffleSplit` are now consistent with `StratifiedShuffleSplit`. Arguments `test_fraction` and `train_fraction` are deprecated and renamed to `test_size` and `train_size` and can accept both `float` and `int`.
- Arguments in class `Bootstrap` are now consistent with `StratifiedShuffleSplit`. Arguments `n_test` and `n_train` are deprecated and renamed to `test_size` and `train_size` and can accept both `float` and `int`.
- Argument `p` added to classes in `Nearest Neighbors` to specify an arbitrary Minkowski metric for nearest neighbors searches.

### 1.7.17 Version 0.10

January 11, 2012

#### Changelog

- Python 2.5 compatibility was dropped; the minimum Python version needed to use scikit-learn is now 2.6.
- *Sparse inverse covariance* estimation using the graph Lasso, with associated cross-validated estimator, by [Gael Varoquaux](#)
- New *Tree* module by [Brian Holt](#), [Peter Prettenhofer](#), [Satrajit Ghosh](#) and [Gilles Louppe](#). The module comes with complete documentation and examples.
- Fixed a bug in the RFE module by [Gilles Louppe](#) (issue #378).
- Fixed a memory leak in *Support Vector Machines* module by [Brian Holt](#) (issue #367).
- Faster tests by [Fabian Pedregosa](#) and others.
- Silhouette Coefficient cluster analysis evaluation metric added as `sklearn.metrics.silhouette_score` by [Robert Layton](#).
- Fixed a bug in *K-means* in the handling of the `n_init` parameter: the clustering algorithm used to be run `n_init` times but the last solution was retained instead of the best solution by [Olivier Grisel](#).
- Minor refactoring in *Stochastic Gradient Descent* module; consolidated dense and sparse predict methods; Enhanced test time performance by converting model parameters to fortran-style arrays after fitting (only multi-class).
- Adjusted Mutual Information metric added as `sklearn.metrics.adjusted_mutual_info_score` by [Robert Layton](#).
- Models like SVC/SVR/LinearSVC/LogisticRegression from libsvm/liblinear now support scaling of C regularization parameter by the number of samples by [Alexandre Gramfort](#).
- New *Ensemble Methods* module by [Gilles Louppe](#) and [Brian Holt](#). The module comes with the random forest algorithm and the extra-trees method, along with documentation and examples.

- *Novelty and Outlier Detection*: outlier and novelty detection, by Virgile Fritsch.
- *Kernel Approximation*: a transform implementing kernel approximation for fast SGD on non-linear kernels by Andreas Müller.
- Fixed a bug due to atom swapping in *Orthogonal Matching Pursuit (OMP)* by Vlad Niculae.
- *Sparse coding with a precomputed dictionary* by Vlad Niculae.
- *Mini Batch K-Means* performance improvements by Olivier Grisel.
- *K-means* support for sparse matrices by Mathieu Blondel.
- Improved documentation for developers and for the `sklearn.utils` module, by Jake Vanderplas.
- Vectorized 20newsgroups dataset loader (`sklearn.datasets.fetch_20newsgroups_vectorized`) by Mathieu Blondel.
- *Multiclass and multilabel algorithms* by Lars Buitinck.
- Utilities for fast computation of mean and variance for sparse matrices by Mathieu Blondel.
- Make `sklearn.preprocessing.scale` and `sklearn.preprocessing.Scaler` work on sparse matrices by Olivier Grisel
- Feature importances using decision trees and/or forest of trees, by Gilles Louppe.
- Parallel implementation of forests of randomized trees by Gilles Louppe.
- `sklearn.cross_validation.ShuffleSplit` can subsample the train sets as well as the test sets by Olivier Grisel.
- Errors in the build of the documentation fixed by Andreas Müller.

## API changes summary

Here are the code migration instructions when upgrading from scikit-learn version 0.9:

- Some estimators that may overwrite their inputs to save memory previously had `overwrite_` parameters; these have been replaced with `copy_` parameters with exactly the opposite meaning.  
This particularly affects some of the estimators in `linear_model`. The default behavior is still to copy everything passed in.
- The SVMlight dataset loader `sklearn.datasets.load_svmlight_file` no longer supports loading two files at once; use `load_svmlight_files` instead. Also, the (unused) `buffer_mb` parameter is gone.
- Sparse estimators in the *Stochastic Gradient Descent* module use dense parameter vector `coef_` instead of `sparse_coef_`. This significantly improves test time performance.
- The *Covariance estimation* module now has a robust estimator of covariance, the Minimum Covariance Determinant estimator.
- Cluster evaluation metrics in `metrics.cluster` have been refactored but the changes are backwards compatible. They have been moved to the `metrics.cluster.supervised`, along with `metrics.cluster.unsupervised` which contains the Silhouette Coefficient.
- The `permutation_test_score` function now behaves the same way as `cross_val_score` (i.e. uses the mean score across the folds.)
- Cross Validation generators now use integer indices (`indices=True`) by default instead of boolean masks. This make it more intuitive to use with sparse matrix data.

- The functions used for sparse coding, `sparse_encode` and `sparse_encode_parallel` have been combined into `sklearn.decomposition.sparse_encode`, and the shapes of the arrays have been transposed for consistency with the matrix factorization setting, as opposed to the regression setting.
- Fixed an off-by-one error in the SVMlight/LibSVM file format handling; files generated using `sklearn.datasets.dump_svmlight_file` should be re-generated. (They should continue to work, but accidentally had one extra column of zeros prepended.)
- `BaseDictionaryLearning` class replaced by `SparseCodingMixin`.
- `sklearn.utils.extmath.fast_svd` has been renamed `sklearn.utils.extmath.randomized_svd` and the default oversampling is now fixed to 10 additional random vectors instead of doubling the number of components to extract. The new behavior follows the reference paper.

## People

- 1 Xinfan Meng

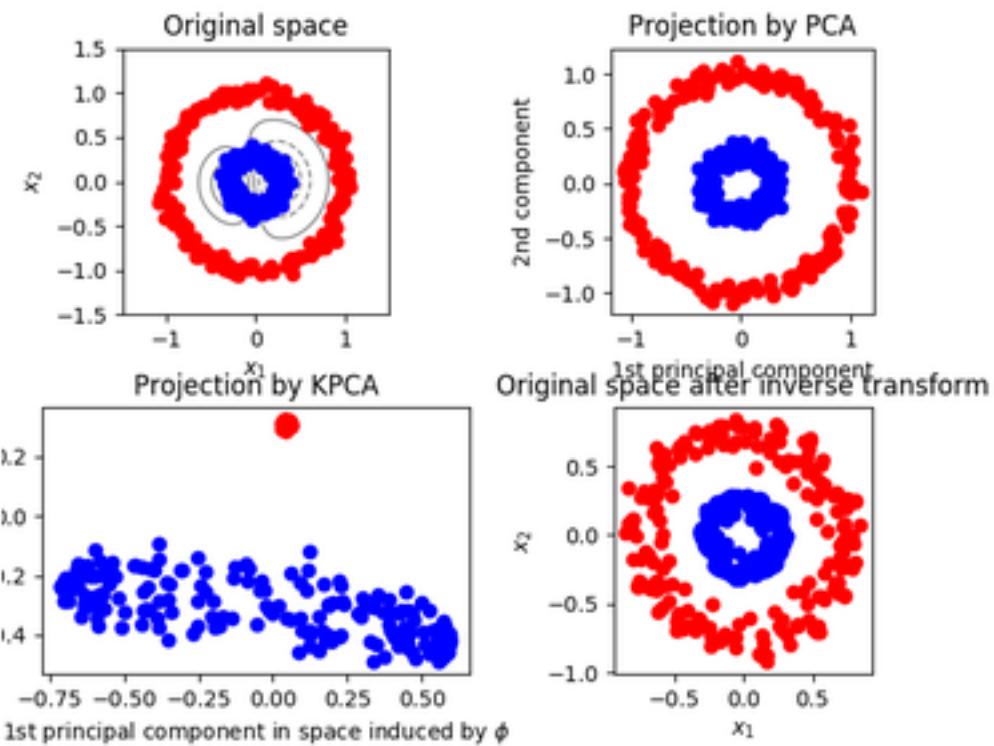

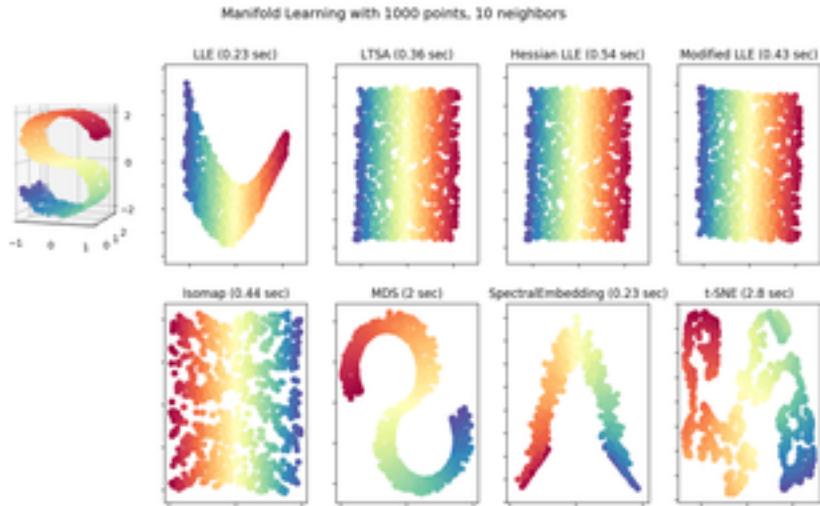

### 1.7.18 Version 0.9

**September 21, 2011**

scikit-learn 0.9 was released on September 2011, three months after the 0.8 release and includes the new modules *Manifold learning*, *The Dirichlet Process* as well as several new algorithms and documentation improvements.

This release also includes the dictionary-learning work developed by [Vlad Niculae](#) as part of the Google Summer of Code program.

## Changelog

- New *Manifold learning* module by Jake Vanderplas and Fabian Pedregosa.
- New *Dirichlet Process Gaussian Mixture Model* by Alexandre Passos

- *Nearest Neighbors* module refactoring by Jake Vanderplas : general refactoring, support for sparse matrices in input, speed and documentation improvements. See the next section for a full list of API changes.
- Improvements on the *Feature selection* module by Gilles Louppe : refactoring of the RFE classes, documentation rewrite, increased efficiency and minor API changes.
- *Sparse principal components analysis (SparsePCA and MiniBatchSparsePCA)* by Vlad Niculae, Gael Varoquaux and Alexandre Gramfort
- Printing an estimator now behaves independently of architectures and Python version thanks to Jean Kossaifi.
- *Loader for libsvm/svmlight format* by Mathieu Blondel and Lars Buitinck
- Documentation improvements: thumbnails in example gallery by Fabian Pedregosa.
- Important bugfixes in *Support Vector Machines* module (segfaults, bad performance) by Fabian Pedregosa.
- Added *Multinomial Naive Bayes* and *Bernoulli Naive Bayes* by Lars Buitinck
- Text feature extraction optimizations by Lars Buitinck
- Chi-Square feature selection (`feature_selection.univariate_selection.chi2`) by Lars Buitinck.
- *Sample generators* module refactoring by Gilles Louppe
- *Multiclass and multilabel algorithms* by Mathieu Blondel
- Ball tree rewrite by Jake Vanderplas
- Implementation of *DBSCAN* algorithm by Robert Layton
- Kmeans predict and transform by Robert Layton
- Preprocessing module refactoring by Olivier Grisel
- Faster mean shift by Conrad Lee
- New Bootstrap, *Random permutations cross-validation a.k.a. Shuffle & Split* and various other improvements in cross validation schemes by Olivier Grisel and Gael Varoquaux
- Adjusted Rand index and V-Measure clustering evaluation metrics by Olivier Grisel
- Added *Orthogonal Matching Pursuit* by Vlad Niculae
- Added 2D-patch extractor utilities in the *Feature extraction* module by Vlad Niculae
- Implementation of `linear_model.LassoLarsCV` (cross-validated Lasso solver using the Lars algorithm) and `linear_model.LassoLarsIC` (BIC/AIC model selection in Lars) by Gael Varoquaux and Alexandre Gramfort
- Scalability improvements to `metrics.roc_curve` by Olivier Hervieu
- Distance helper functions `metrics.pairwise.pairwise_distances` and `metrics.pairwise.pairwise_kernels` by Robert Layton
- *Mini-Batch K-Means* by Nelle Varoquaux and Peter Prettenhofer.
- *Downloading datasets from the mldata.org repository* utilities by Pietro Berkes.
- *The Olivetti faces dataset* by David Warde-Farley.

## API changes summary

Here are the code migration instructions when upgrading from scikit-learn version 0.8:

- The `scikits.learn` package was renamed `sklearn`. There is still a `scikits.learn` package alias for backward compatibility.

Third-party projects with a dependency on scikit-learn 0.9+ should upgrade their codebase. For instance, under Linux / MacOSX just run (make a backup first!):

```
find -name "*.py" | xargs sed -i 's/\bscikits.learn\b/sklearn/g'
```

- Estimators no longer accept model parameters as `fit` arguments: instead all parameters must be only be passed as constructor arguments or using the now public `set_params` method inherited from `base.BaseEstimator`.

Some estimators can still accept keyword arguments on the `fit` but this is restricted to data-dependent values (e.g. a Gram matrix or an affinity matrix that are precomputed from the `X` data matrix).

- The `cross_val` package has been renamed to `cross_validation` although there is also a `cross_val` package alias in place for backward compatibility.

Third-party projects with a dependency on scikit-learn 0.9+ should upgrade their codebase. For instance, under Linux / MacOSX just run (make a backup first!):

```
find -name "*.py" | xargs sed -i 's/\bcross_val\b/cross_validation/g'
```

- The `score_func` argument of the `sklearn.cross_validation.cross_val_score` function is now expected to accept `y_test` and `y_predicted` as only arguments for classification and regression tasks or `X_test` for unsupervised estimators.
- `gamma` parameter for support vector machine algorithms is set to `1 / n_features` by default, instead of `1 / n_samples`.
- The `sklearn.hmm` has been marked as orphaned: it will be removed from scikit-learn in version 0.11 unless someone steps up to contribute documentation, examples and fix lurking numerical stability issues.
- `sklearn.neighbors` has been made into a submodule. The two previously available estimators, `NeighborsClassifier` and `NeighborsRegressor` have been marked as deprecated. Their functionality has been divided among five new classes: `NearestNeighbors` for unsupervised neighbors searches, `KNeighborsClassifier` & `RadiusNeighborsClassifier` for supervised classification problems, and `KNeighborsRegressor` & `RadiusNeighborsRegressor` for supervised regression problems.
- `sklearn.ball_tree.BallTree` has been moved to `sklearn.neighbors.BallTree`. Using the former will generate a warning.
- `sklearn.linear_model.LARS()` and related classes (`LassoLARS`, `LassoLARSCV`, etc.) have been renamed to `sklearn.linear_model.Lars()`.
- All distance metrics and kernels in `sklearn.metrics.pairwise` now have a `Y` parameter, which by default is `None`. If not given, the result is the distance (or kernel similarity) between each sample in `Y`. If given, the result is the pairwise distance (or kernel similarity) between samples in `X` to `Y`.
- `sklearn.metrics.pairwise.l1_distance` is now called `manhattan_distance`, and by default returns the pairwise distance. For the component wise distance, set the parameter `sum_over_features` to `False`.

Backward compatibility package aliases and other deprecated classes and functions will be removed in version 0.11.

## 1.7.19 Version 0.8

May 11, 2011

scikit-learn 0.8 was released on May 2011, one month after the first “international” scikit-learn coding sprint and is marked by the inclusion of important modules: *Hierarchical clustering*, *Cross decomposition*, *Non-negative matrix factorization (NMF or NNMF)*, initial support for Python 3 and by important enhancements and bug fixes.

### Changelog

Several new modules where introduced during this release:

- New *Hierarchical clustering* module by Vincent Michel, Bertrand Thirion, Alexandre Gramfort and Gael Varoquaux.
- *Kernel PCA* implementation by Mathieu Blondel
- *The Labeled Faces in the Wild* face recognition dataset by Olivier Grisel.
- New *Cross decomposition* module by Edouard Duchiensay.
- *Non-negative matrix factorization (NMF or NNMF)* module Vlad Niculae
- Implementation of the *Oracle Approximating Shrinkage* algorithm by Virgile Fritsch in the *Covariance estimation* module.

Some other modules benefited from significant improvements or cleanups.

- Initial support for Python 3: builds and imports cleanly, some modules are usable while others have failing tests by Fabian Pedregosa.
- *decomposition.PCA* is now usable from the Pipeline object by Olivier Grisel.
- Guide *How to optimize for speed* by Olivier Grisel.
- Fixes for memory leaks in libsvm bindings, 64-bit safer BallTree by Lars Buitinck.
- bug and style fixing in *K-means* algorithm by Jan Schlüter.
- Add attribute converged to Gaussian Mixture Models by Vincent Schut.
- Implemented `transform`, `predict_log_proba` in *discriminant\_analysis*. *LinearDiscriminantAnalysis* By Mathieu Blondel.
- Refactoring in the *Support Vector Machines* module and bug fixes by Fabian Pedregosa, Gael Varoquaux and Amit Aides.
- Refactored SGD module (removed code duplication, better variable naming), added interface for sample weight by Peter Prettenhofer.
- Wrapped BallTree with Cython by Thouis (Ray) Jones.
- Added function *svm.11\_min\_c* by Paolo Losi.
- Typos, doc style, etc. by Yaroslav Halchenko, Gael Varoquaux, Olivier Grisel, Yann Malet, Nicolas Pinto, Lars Buitinck and Fabian Pedregosa.

## 1.7.20 Version 0.7

**March 2, 2011**

scikit-learn 0.7 was released in March 2011, roughly three months after the 0.6 release. This release is marked by the speed improvements in existing algorithms like k-Nearest Neighbors and K-Means algorithm and by the inclusion of an efficient algorithm for computing the Ridge Generalized Cross Validation solution. Unlike the preceding release, no new modules where added to this release.

### Changelog

- Performance improvements for Gaussian Mixture Model sampling [Jan Schlüter].
- Implementation of efficient leave-one-out cross-validated Ridge in `linear_model.RidgeCV` [Mathieu Blondel]

- Better handling of collinearity and early stopping in `linear_model.lars_path` [Alexandre Gramfort and Fabian Pedregosa].
- Fixes for liblinear ordering of labels and sign of coefficients [Dan Yamins, Paolo Losi, Mathieu Blondel and Fabian Pedregosa].
- Performance improvements for Nearest Neighbors algorithm in high-dimensional spaces [Fabian Pedregosa].
- Performance improvements for `cluster.KMeans` [Gael Varoquaux and James Bergstra].
- Sanity checks for SVM-based classes [Mathieu Blondel].
- Refactoring of `neighbors.NeighborsClassifier` and `neighbors.kneighbors_graph`: added different algorithms for the k-Nearest Neighbor Search and implemented a more stable algorithm for finding barycenter weights. Also added some developer documentation for this module, see `notes_neighbors` for more information [Fabian Pedregosa].
- Documentation improvements: Added `pca.RandomizedPCA` and `linear_model.LogisticRegression` to the class reference. Also added references of matrices used for clustering and other fixes [Gael Varoquaux, Fabian Pedregosa, Mathieu Blondel, Olivier Grisel, Virgile Fritsch, Emmanuelle Gouillart]
- Binded `decision_function` in classes that make use of liblinear, dense and sparse variants, like `svm.LinearSVC` or `linear_model.LogisticRegression` [Fabian Pedregosa].
- Performance and API improvements to `metrics.euclidean_distances` and to `pca.RandomizedPCA` [James Bergstra].
- Fix compilation issues under NetBSD [Kamel Ibn Hassen Derouiche]
- Allow input sequences of different lengths in `hmm.GaussianHMM` [Ron Weiss].
- Fix bug in affinity propagation caused by incorrect indexing [Xinfan Meng]

## 1.7.21 Version 0.6

**December 21, 2010**

scikit-learn 0.6 was released on December 2010. It is marked by the inclusion of several new modules and a general renaming of old ones. It is also marked by the inclusion of new example, including applications to real-world datasets.

### Changelog

- New *stochastic gradient* descent module by Peter Prettenhofer. The module comes with complete documentation and examples.
- Improved *svm* module: memory consumption has been reduced by 50%, heuristic to automatically set class weights, possibility to assign weights to samples (see [SVM: Weighted samples](#) for an example).
- New *Gaussian Processes* module by Vincent Dubourg. This module also has great documentation and some very neat examples. See `example_gaussian_process_plot_gp_regression.py` or `example_gaussian_process_plot_gp_probabilistic_classification_after_regression.py` for a taste of what can be done.
- It is now possible to use liblinear's Multi-class SVC (option `multi_class` in [`svm.LinearSVC`](#))
- New features and performance improvements of text feature extraction.
- Improved sparse matrix support, both in main classes ([`grid\_search.GridSearchCV`](#)) as in modules `sklearn.svm.sparse` and `sklearn.linear_model.sparse`.
- Lots of cool new examples and a new section that uses real-world datasets was created. These include: `sphx_glr_auto_examples_applications_face_recognition.py`, [Species distribution modeling](#), [Libsvm GUI](#), [Wikipedia principal eigenvector](#) and others.
- Faster *Least Angle Regression* algorithm. It is now 2x faster than the R version on worst case and up to 10x times faster on some cases.
- Faster coordinate descent algorithm. In particular, the full path version of lasso ([`linear\_model.lasso\_path`](#)) is more than 200x times faster than before.
- It is now possible to get probability estimates from a [`linear\_model.LogisticRegression`](#) model.
- module renaming: the `glm` module has been renamed to `linear_model`, the `gmm` module has been included into the more general mixture model and the `sgd` module has been included in `linear_model`.
- Lots of bug fixes and documentation improvements.

### People

## 1.7.22 Version 0.5

October 11, 2010

### Changelog

#### New classes

- Support for sparse matrices in some classifiers of modules `svm` and `linear_model` (see `svm.sparse.SVC`, `svm.sparse.SVR`, `svm.sparse.LinearSVC`, `linear_model.sparse.Lasso`, `linear_model.sparse.ElasticNet`)
- New `pipeline.Pipeline` object to compose different estimators.
- Recursive Feature Elimination routines in module *Feature selection*.
- Addition of various classes capable of cross validation in the `linear_model` module (`linear_model.LassoCV`, `linear_model.ElasticNetCV`, etc.).
- New, more efficient LARS algorithm implementation. The Lasso variant of the algorithm is also implemented. See `linear_model.lars_path`, `linear_model.Lars` and `linear_model.LassoLars`.
- New Hidden Markov Models module (see classes `hmm.GaussianHMM`, `hmm.MultinomialHMM`, `hmm.GMMHMM`)
- New module `feature_extraction` (see *class reference*)
- New FastICA algorithm in module `sklearn.fastica`

### Documentation

- Improved documentation for many modules, now separating narrative documentation from the class reference. As an example, see [documentation for the SVM module](#) and the complete [class reference](#).

### Fixes

- API changes: adhere variable names to PEP-8, give more meaningful names.
- Fixes for `svm` module to run on a shared memory context (multiprocessing).
- It is again possible to generate latex (and thus PDF) from the sphinx docs.

## Examples

- new examples using some of the mlcomp datasets: `sphx_glr_auto_examples_mlcomp_sparse_document_classification.py` (since removed) and [\*Classification of text documents using sparse features\*](#)
- Many more examples. See [here](#) the full list of examples.

## External dependencies

- Joblib is now a dependency of this package, although it is shipped with (`sklearn.externals.joblib`).

## Removed modules

- Module ann (Artificial Neural Networks) has been removed from the distribution. Users wanting this sort of algorithms should take a look into pybrain.

## Misc

- New sphinx theme for the web page.

## Authors

The following is a list of authors for this release, preceded by number of commits:

- 262 Fabian Pedregosa
- 240 Gael Varoquaux
- 149 Alexandre Gramfort
- 116 Olivier Grisel
- 40 Vincent Michel
- 38 Ron Weiss
- 23 Matthieu Perrot
- 10 Bertrand Thirion
- 7 Yaroslav Halchenko
- 9 VirgileFritsch
- 6 Edouard Duchesnay
- 4 Mathieu Blondel
- 1 Ariel Rokem
- 1 Matthieu Brucher

## 1.7.23 Version 0.4

August 26, 2010

## Changelog

Major changes in this release include:

- Coordinate Descent algorithm (Lasso, ElasticNet) refactoring & speed improvements (roughly 100x times faster).
- Coordinate Descent Refactoring (and bug fixing) for consistency with R's package GLMNET.
- New metrics module.
- New GMM module contributed by Ron Weiss.
- Implementation of the LARS algorithm (without Lasso variant for now).
- feature\_selection module redesign.
- Migration to GIT as version control system.
- Removal of obsolete attrselect module.
- Rename of private compiled extensions (added underscore).
- Removal of legacy unmaintained code.
- Documentation improvements (both docstring and rst).
- Improvement of the build system to (optionally) link with MKL. Also, provide a lite BLAS implementation in case no system-wide BLAS is found.
- Lots of new examples.
- Many, many bug fixes ...

## Authors

The committer list for this release is the following (preceded by number of commits):

- 143 Fabian Pedregosa
- 35 Alexandre Gramfort
- 34 Olivier Grisel
- 11 Gael Varoquaux
- 5 Yaroslav Halchenko
- 2 Vincent Michel
- 1 Chris Filo Gorgolewski

### 1.7.24 Earlier versions

Earlier versions included contributions by Fred Mailhot, David Cooke, David Huard, Dave Morrill, Ed Schofield, Travis Oliphant, Pearu Peterson.

## SCIKIT-LEARN TUTORIALS

### 2.1 An introduction to machine learning with scikit-learn

#### Section contents

In this section, we introduce the [machine learning](#) vocabulary that we use throughout scikit-learn and give a simple learning example.

#### 2.1.1 Machine learning: the problem setting

In general, a learning problem considers a set of  $n$  [samples](#) of data and then tries to predict properties of unknown data. If each sample is more than a single number and, for instance, a multi-dimensional entry (aka [multivariate](#) data), it is said to have several attributes or [features](#).

We can separate learning problems in a few large categories:

- [supervised learning](#), in which the data comes with additional attributes that we want to predict ([Click here](#) to go to the scikit-learn supervised learning page). This problem can be either:
  - [classification](#): samples belong to two or more classes and we want to learn from already labeled data how to predict the class of unlabeled data. An example of classification problem would be the handwritten digit recognition example, in which the aim is to assign each input vector to one of a finite number of discrete categories. Another way to think of classification is as a discrete (as opposed to continuous) form of supervised learning where one has a limited number of categories and for each of the  $n$  samples provided, one is to try to label them with the correct category or class.
  - [regression](#): if the desired output consists of one or more continuous variables, then the task is called [regression](#). An example of a regression problem would be the prediction of the length of a salmon as a function of its age and weight.
- [unsupervised learning](#), in which the training data consists of a set of input vectors  $x$  without any corresponding target values. The goal in such problems may be to discover groups of similar examples within the data, where it is called [clustering](#), or to determine the distribution of data within the input space, known as [density estimation](#), or to project the data from a high-dimensional space down to two or three dimensions for the purpose of [visualization](#) ([Click here](#) to go to the Scikit-Learn unsupervised learning page).

### Training set and testing set

Machine learning is about learning some properties of a data set and applying them to new data. This is why a common practice in machine learning to evaluate an algorithm is to split the data at hand into two sets, one that we call the **training set** on which we learn data properties and one that we call the **testing set** on which we test these properties.

## 2.1.2 Loading an example dataset

*scikit-learn* comes with a few standard datasets, for instance the `iris` and `digits` datasets for classification and the `boston house prices dataset` for regression.

In the following, we start a Python interpreter from our shell and then load the `iris` and `digits` datasets. Our notational convention is that \$ denotes the shell prompt while >>> denotes the Python interpreter prompt:

```
$ python
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> digits = datasets.load_digits()
```

A dataset is a dictionary-like object that holds all the data and some metadata about the data. This data is stored in the `.data` member, which is a `n_samples`, `n_features` array. In the case of supervised problem, one or more response variables are stored in the `.target` member. More details on the different datasets can be found in the [dedicated section](#).

For instance, in the case of the `digits` dataset, `digits.data` gives access to the features that can be used to classify the `digits` samples:

```
>>> print(digits.data)
[[ 0.   0.   5. ...,  0.   0.   0.]
 [ 0.   0.   0. ..., 10.   0.   0.]
 [ 0.   0.   0. ..., 16.   9.   0.]
 ...
 [ 0.   0.   1. ...,  6.   0.   0.]
 [ 0.   0.   2. ..., 12.   0.   0.]
 [ 0.   0.   10. ..., 12.   1.   0.]]
```

and `digits.target` gives the ground truth for the digit dataset, that is the number corresponding to each digit image that we are trying to learn:

```
>>> digits.target
array([0, 1, 2, ..., 8, 9, 8])
```

### Shape of the data arrays

The data is always a 2D array, shape `(n_samples, n_features)`, although the original data may have had a different shape. In the case of the `digits`, each original sample is an image of shape `(8, 8)` and can be accessed using:

```
>>> digits.images[0]
array([[ 0.,  0.,  5., 13.,  9.,  1.,  0.,  0.],
       [ 0.,  0., 13., 15., 10., 15.,  5.,  0.],
       [ 0.,  3., 15.,  2.,  0., 11.,  8.,  0.],
       [ 0.,  4., 12.,  0.,  0.,  8.,  8.,  0.],
       [ 0.,  5.,  8.,  0.,  0.,  9.,  8.,  0.],
       [ 0.,  4., 11.,  0.,  1., 12.,  7.,  0.],
       [ 0.,  2., 14.,  5., 10., 12.,  0.,  0.],
       [ 0.,  0.,  6., 13., 10.,  0.,  0.,  0.]])
```

The [simple example on this dataset](#) illustrates how starting from the original problem one can shape the data for consumption in scikit-learn.

### Loading from external datasets

To load from an external dataset, please refer to [loading external datasets](#).

## 2.1.3 Learning and predicting

In the case of the digits dataset, the task is to predict, given an image, which digit it represents. We are given samples of each of the 10 possible classes (the digits zero through nine) on which we *fit* an estimator to be able to *predict* the classes to which unseen samples belong.

In scikit-learn, an estimator for classification is a Python object that implements the methods `fit(X, y)` and `predict(T)`.

An example of an estimator is the class `sklearn.svm.SVC` that implements [support vector classification](#). The constructor of an estimator takes as arguments the parameters of the model, but for the time being, we will consider the estimator as a black box:

```
>>> from sklearn import svm
>>> clf = svm.SVC(gamma=0.001, C=100.)
```

### Choosing the parameters of the model

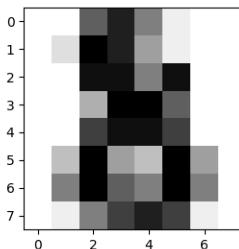

In this example we set the value of `gamma` manually. It is possible to automatically find good values for the parameters by using tools such as [grid search](#) and [cross validation](#).

We call our estimator instance `clf`, as it is a classifier. It now must be fitted to the model, that is, it must *learn* from the model. This is done by passing our training set to the `fit` method. As a training set, let us use all the images of our dataset apart from the last one. We select this training set with the `[:-1]` Python syntax, which produces a new array that contains all but the last entry of `digits.data`:

```
>>> clf.fit(digits.data[:-1], digits.target[:-1])
SVC(C=100.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma=0.001, kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)
```

Now you can predict new values, in particular, we can ask to the classifier what is the digit of our last image in the `digits` dataset, which we have not used to train the classifier:

```
>>> clf.predict(digits.data[-1:])
array([8])
```

The corresponding image is the following:  
The images are of poor resolution. Do you agree with the classifier?

As you can see, it is a challenging task: the

A complete example of this classification problem is available as an example that you can run and study: [Recognizing hand-written digits](#).

## 2.1.4 Model persistence

It is possible to save a model in the scikit by using Python's built-in persistence model, namely [pickle](#):

```
>>> from sklearn import svm
>>> from sklearn import datasets
>>> clf = svm.SVC()
>>> iris = datasets.load_iris()
>>> X, y = iris.data, iris.target
>>> clf.fit(X, y)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)

>>> import pickle
>>> s = pickle.dumps(clf)
>>> clf2 = pickle.loads(s)
>>> clf2.predict(X[0:1])
array([0])
>>> y[0]
0
```

In the specific case of the scikit, it may be more interesting to use joblib's replacement of pickle (`joblib.dump` & `joblib.load`), which is more efficient on big data, but can only pickle to the disk and not to a string:

```
>>> from sklearn.externals import joblib
>>> joblib.dump(clf, 'filename.pkl')
```

Later you can load back the pickled model (possibly in another Python process) with:

```
>>> clf = joblib.load('filename.pkl')
```

---

**Note:** `joblib.dump` and `joblib.load` functions also accept file-like object instead of filenames. More information on data persistence with Joblib is available [here](#).

Note that pickle has some security and maintainability issues. Please refer to section [Model persistence](#) for more detailed information about model persistence with scikit-learn.

## 2.1.5 Conventions

scikit-learn estimators follow certain rules to make their behavior more predictive.

### Type casting

Unless otherwise specified, input will be cast to `float64`:

```
>>> import numpy as np
>>> from sklearn import random_projection

>>> rng = np.random.RandomState(0)
>>> X = rng.rand(10, 2000)
>>> X = np.array(X, dtype='float32')
>>> X.dtype
dtype('float32')

>>> transformer = random_projection.GaussianRandomProjection()
>>> X_new = transformer.fit_transform(X)
>>> X_new.dtype
dtype('float64')
```

In this example, `X` is `float32`, which is cast to `float64` by `fit_transform(X)`.

Regression targets are cast to `float64`, classification targets are maintained:

```
>>> from sklearn import datasets
>>> from sklearn.svm import SVC
>>> iris = datasets.load_iris()
>>> clf = SVC()
>>> clf.fit(iris.data, iris.target)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)

>>> list(clf.predict(iris.data[:3]))
[0, 0, 0]

>>> clf.fit(iris.data, iris.target_names[iris.target])
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)

>>> list(clf.predict(iris.data[:3]))
['setosa', 'setosa', 'setosa']
```

Here, the first `predict()` returns an integer array, since `iris.target` (an integer array) was used in `fit`. The second `predict()` returns a string array, since `iris.target_names` was for fitting.

### Refitting and updating parameters

Hyper-parameters of an estimator can be updated after it has been constructed via the `sklearn.pipeline.Pipeline.set_params` method. Calling `fit()` more than once will overwrite what was learned by any previous `fit()`:

```
>>> import numpy as np
>>> from sklearn.svm import SVC

>>> rng = np.random.RandomState(0)
>>> X = rng.rand(100, 10)
>>> y = rng.binomial(1, 0.5, 100)
>>> X_test = rng.rand(5, 10)

>>> clf = SVC()
>>> clf.set_params(kernel='linear').fit(X, y)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='linear',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)
>>> clf.predict(X_test)
array([1, 0, 1, 1, 0])

>>> clf.set_params(kernel='rbf').fit(X, y)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)
>>> clf.predict(X_test)
array([0, 0, 0, 1, 0])
```

Here, the default kernel `rbf` is first changed to `linear` after the estimator has been constructed via `SVC()`, and changed back to `rbf` to refit the estimator and to make a second prediction.

## Multiclass vs. multilabel fitting

When using *multiclass classifiers*, the learning and prediction task that is performed is dependent on the format of the target data fit upon:

```
>>> from sklearn.svm import SVC
>>> from sklearn.multiclass import OneVsRestClassifier
>>> from sklearn.preprocessing import LabelBinarizer

>>> X = [[1, 2], [2, 4], [4, 5], [3, 2], [3, 1]]
>>> y = [0, 0, 1, 1, 2]

>>> classif = OneVsRestClassifier(estimator=SVC(random_state=0))
>>> classif.fit(X, y).predict(X)
array([0, 0, 1, 1, 2])
```

In the above case, the classifier is fit on a 1d array of multiclass labels and the `predict()` method therefore provides corresponding multiclass predictions. It is also possible to fit upon a 2d array of binary label indicators:

```
>>> y = LabelBinarizer().fit_transform(y)
>>> classif.fit(X, y).predict(X)
array([[1, 0, 0],
       [1, 0, 0],
       [0, 1, 0],
       [0, 0, 0],
       [0, 0, 0]])
```

Here, the classifier is `fit()` on a 2d binary label representation of `y`, using the `LabelBinarizer`. In this case `predict()` returns a 2d array representing the corresponding multilabel predictions.

Note that the fourth and fifth instances returned all zeroes, indicating that they matched none of the three labels fit upon. With multilabel outputs, it is similarly possible for an instance to be assigned multiple labels:

```
>> from sklearn.preprocessing import MultiLabelBinarizer
>> y = [[0, 1], [0, 2], [1, 3], [0, 2, 3], [2, 4]]
>> y = MultiLabelBinarizer().fit_transform(y)
>> classif.fit(X, y).predict(X)
array([[1, 0, 0, 0],
       [1, 0, 1, 0],
       [0, 1, 0, 1, 0],
       [1, 0, 1, 1, 0],
       [0, 0, 1, 0, 1]])
```

In this case, the classifier is fit upon instances each assigned multiple labels. The `MultiLabelBinarizer` is used to binarize the 2d array of multilabels to fit upon. As a result, `predict()` returns a 2d array with multiple predicted labels for each instance.

## 2.2 A tutorial on statistical-learning for scientific data processing

### Statistical learning

Machine learning is a technique with a growing importance, as the size of the datasets experimental sciences are facing is rapidly growing. Problems it tackles range from building a prediction function linking different observations, to classifying observations, or learning the structure in an unlabeled dataset.

This tutorial will explore *statistical learning*, the use of machine learning techniques with the goal of *statistical inference*: drawing conclusions on the data at hand.

Scikit-learn is a Python module integrating classic machine learning algorithms in the tightly-knit world of scientific Python packages (`NumPy`, `SciPy`, `matplotlib`).

### 2.2.1 Statistical learning: the setting and the estimator object in scikit-learn

#### Datasets

Scikit-learn deals with learning information from one or more datasets that are represented as 2D arrays. They can be understood as a list of multi-dimensional observations. We say that the first axis of these arrays is the **samples** axis, while the second is the **features** axis.

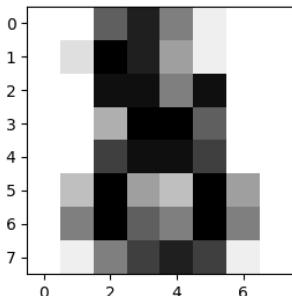

#### A simple example shipped with the scikit: iris dataset

```
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> data = iris.data
>>> data.shape
(150, 4)
```

It is made of 150 observations of irises, each described by 4 features: their sepal and petal length and width, as detailed in `iris.DESCR`.

When the data is not initially in the `(n_samples, n_features)` shape, it needs to be preprocessed in order to be used by scikit-learn.

### An example of reshaping data would be the digits dataset

The digits dataset is made of 1797 8x8 images of hand-written digits

```
>>> digits = datasets.load_digits()
>>> digits.images.shape
(1797, 8, 8)
>>> import matplotlib.pyplot as plt
>>> plt.imshow(digits.images[-1], cmap=plt.cm.gray_r)
<matplotlib.image.AxesImage object at ...>
```

To use this dataset with the scikit, we transform each 8x8 image into a feature vector of length 64

```
>>> data = digits.images.reshape((digits.images.shape[0], -1))
```

## Estimators objects

**Fitting data:** the main API implemented by scikit-learn is that of the *estimator*. An estimator is any object that learns from data; it may be a classification, regression or clustering algorithm or a *transformer* that extracts/filters useful features from raw data.

All estimator objects expose a `fit` method that takes a dataset (usually a 2-d array):

```
>>> estimator.fit(data)
```

**Estimator parameters:** All the parameters of an estimator can be set when it is instantiated or by modifying the corresponding attribute:

```
>>> estimator = Estimator(param1=1, param2=2)
>>> estimator.param1
1
```

**Estimated parameters:** When data is fitted with an estimator, parameters are estimated from the data at hand. All the estimated parameters are attributes of the estimator object ending by an underscore:

```
>>> estimator.estimated_param_
```

## 2.2.2 Supervised learning: predicting an output variable from high-dimensional observations

### The problem solved in supervised learning

*Supervised learning* consists in learning the link between two datasets: the observed data  $X$  and an external variable  $y$  that we are trying to predict, usually called “target” or “labels”. Most often,  $y$  is a 1D array of length  $n_{\text{samples}}$ .

All supervised [estimators](#) in scikit-learn implement a `fit(X, y)` method to fit the model and a `predict(X)` method that, given unlabeled observations  $X$ , returns the predicted labels  $y$ .

### Vocabulary: classification and regression

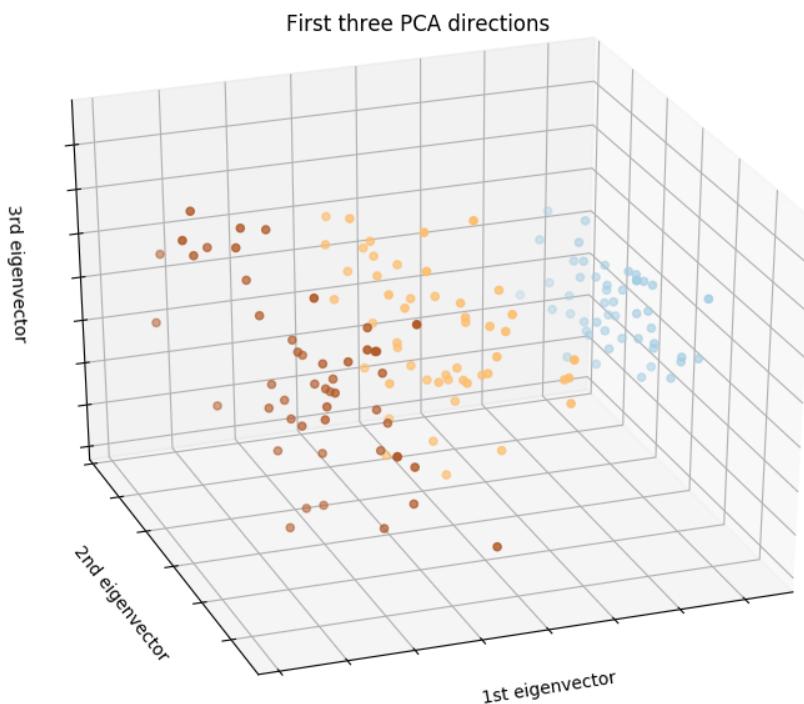

If the prediction task is to classify the observations in a set of finite labels, in other words to “name” the objects observed, the task is said to be a **classification** task. On the other hand, if the goal is to predict a continuous target variable, it is said to be a **regression** task.

When doing classification in scikit-learn,  $y$  is a vector of integers or strings.

Note: See the [Introduction to machine learning with scikit-learn Tutorial](#) for a quick run-through on the basic machine learning vocabulary used within scikit-learn.

## Nearest neighbor and the curse of dimensionality

### Classifying irises:

The iris dataset is a classification task consisting in identifying 3 different types of irises (Setosa, Versicolour, and Virginica) from their petal and sepal length and width:

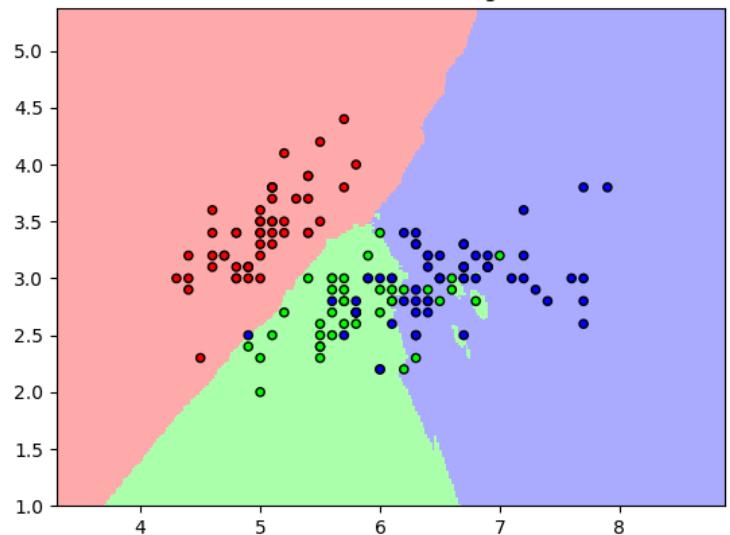

```
>>> import numpy as np
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> iris_X = iris.data
>>> iris_y = iris.target
>>> np.unique(iris_y)
array([0, 1, 2])
```

## k-Nearest neighbors classifier

The simplest possible classifier is the [nearest neighbor](#): given a new observation  $X_{\text{test}}$ , find in the training set (i.e. the data used to train the estimator) the observation with the closest feature vector. (Please see the [Nearest Neighbors section](#) of the online Scikit-learn documentation for more information about this type of classifier.)

### Training set and testing set

While experimenting with any learning algorithm, it is important not to test the prediction of an estimator on the data used to fit the estimator as this would not be evaluating the performance of the estimator on **new data**. This is why datasets are often split into *train* and *test* data.

3-Class classification ( $k = 15$ , weights = 'uniform')

### KNN (k nearest neighbors) classification example:

```
>>> # Split iris data in train and test data
>>> # A random permutation, to split the data randomly
>>> np.random.seed(0)
>>> indices = np.random.permutation(len(iris_X))
>>> iris_X_train = iris_X[indices[:-10]]
>>> iris_y_train = iris_y[indices[:-10]]
>>> iris_X_test = iris_X[indices[-10:]]
>>> iris_y_test = iris_y[indices[-10:]]
>>> # Create and fit a nearest-neighbor classifier
>>> from sklearn.neighbors import KNeighborsClassifier
>>> knn = KNeighborsClassifier()
>>> knn.fit(iris_X_train, iris_y_train)
KNeighborsClassifier(algorithm='auto', leaf_size=30, metric='minkowski',
                     metric_params=None, n_jobs=1, n_neighbors=5, p=2,
                     weights='uniform')
>>> knn.predict(iris_X_test)
array([1, 2, 1, 0, 0, 0, 2, 1, 2, 0])
>>> iris_y_test
array([1, 1, 1, 0, 0, 0, 2, 1, 2, 0])
```

### The curse of dimensionality

For an estimator to be effective, you need the distance between neighboring points to be less than some value  $d$ , which depends on the problem. In one dimension, this requires on average  $n \sim 1/d$  points. In the context of the above  $k$ -NN example, if the data is described by just one feature with values ranging from 0 to 1 and with  $n$  training observations, then new data will be no further away than  $1/n$ . Therefore, the nearest neighbor decision rule will be efficient as soon as  $1/n$  is small compared to the scale of between-class feature variations.

If the number of features is  $p$ , you now require  $n \sim 1/d^p$  points. Let's say that we require 10 points in one dimension: now  $10^p$  points are required in  $p$  dimensions to pave the  $[0, 1]$  space. As  $p$  becomes large, the number of training points required for a good estimator grows exponentially.

For example, if each point is just a single number (8 bytes), then an effective  $k$ -NN estimator in a paltry  $p \sim 20$  dimensions would require more training data than the current estimated size of the entire internet ( $\pm 1000$  Exabytes or

so).

This is called the [curse of dimensionality](#) and is a core problem that machine learning addresses.

## Linear model: from regression to sparsity

### Diabetes dataset

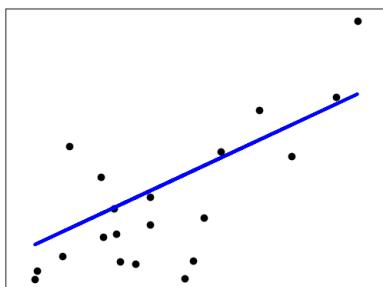

The diabetes dataset consists of 10 physiological variables (age, sex, weight, blood pressure) measure on 442 patients, and an indication of disease progression after one year:

```
>>> diabetes = datasets.load_diabetes()
>>> diabetes_X_train = diabetes.data[:-20]
>>> diabetes_X_test = diabetes.data[-20:]
>>> diabetes_y_train = diabetes.target[:-20]
>>> diabetes_y_test = diabetes.target[-20:]
```

The task at hand is to predict disease progression from physiological variables.

## Linear regression

[LinearRegression](#), in its simplest form, fits a linear model to the data set by adjusting a set of parameters in order to make the sum of the squared residuals of the model as small as possible.

Linear models:  $y = X\beta + \epsilon$

- $X$ : data
- $y$ : target variable
- $\beta$ : Coefficients
- $\epsilon$ : Observation noise

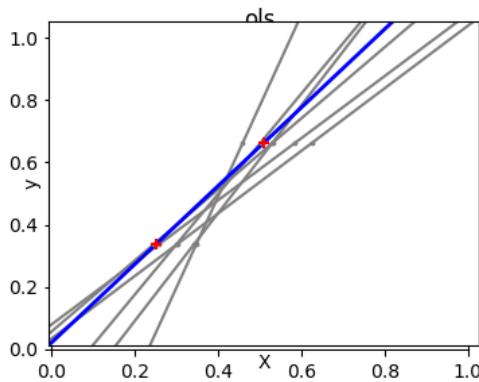

```
>>> from sklearn import linear_model
>>> regr = linear_model.LinearRegression()
>>> regr.fit(diabetes_X_train, diabetes_y_train)
LinearRegression(copy_X=True, fit_intercept=True, n_jobs=1, normalize=False)
>>> print(regr.coef_)
[ 0.30349955 -237.63931533  510.53060544  327.73698041 -814.13170937
 492.81458798  102.84845219  184.60648906  743.51961675   76.09517222]

>>> # The mean square error
>>> np.mean((regr.predict(diabetes_X_test)-diabetes_y_test)**2)
2004.56760268...
```

```
>>> # Explained variance score: 1 is perfect prediction
>>> # and 0 means that there is no linear relationship
>>> # between X and y.
>>> regr.score(diabetes_X_test, diabetes_y_test)
0.5850753022690...
```

## Shrinkage

If there are few data points per dimension, noise in the observations induces high variance:

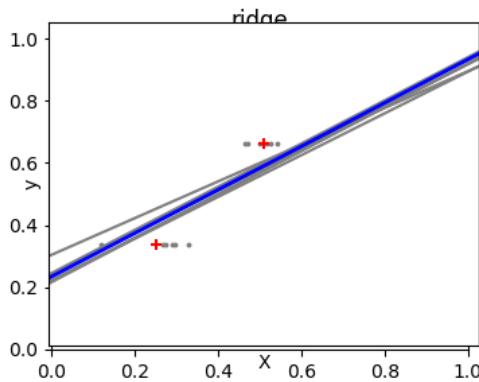

```
>>> X = np.c_[ .5, 1].T
>>> y = [.5, 1]
>>> test = np.c_[ 0, 2].T
>>> regr = linear_model.LinearRegression()

>>> import matplotlib.pyplot as plt
>>> plt.figure()

>>> np.random.seed(0)
>>> for _ in range(6):
...     this_X = .1*np.random.normal(size=(2, 1)) + X
...     regr.fit(this_X, y)
...     plt.plot(test, regr.predict(test))
...     plt.scatter(this_X, y, s=3)
```

A solution in high-dimensional statistical learning is to *shrink* the regression coefficients to zero: any two randomly chosen set of observations are likely to be uncorrelated. This is called *Ridge* regression:

```
>>> regr = linear_model.Ridge(alpha=.1)

>>> plt.figure()

>>> np.random.seed(0)
>>> for _ in range(6):
...     this_X = .1*np.random.normal(size=(2, 1)) + X
...     regr.fit(this_X, y)
...     plt.plot(test, regr.predict(test))
...     plt.scatter(this_X, y, s=3)
```

This is an example of **bias/variance tradeoff**: the larger the ridge alpha parameter, the higher the bias and the lower the variance.

We can choose alpha to minimize left out error, this time using the diabetes dataset rather than our synthetic data:

```
>>> alphas = np.logspace(-4, -1, 6)
>>> from __future__ import print_function
>>> print([regr.set_params(alpha=alpha
...         ).fit(diabetes_X_train, diabetes_y_train,
...         ).score(diabetes_X_test, diabetes_y_test) for alpha in alphas])
[0.5851110683883..., 0.5852073015444..., 0.5854677540698..., 0.5855512036503..., 0.
˓→5830717085554..., 0.57058999437...]
```

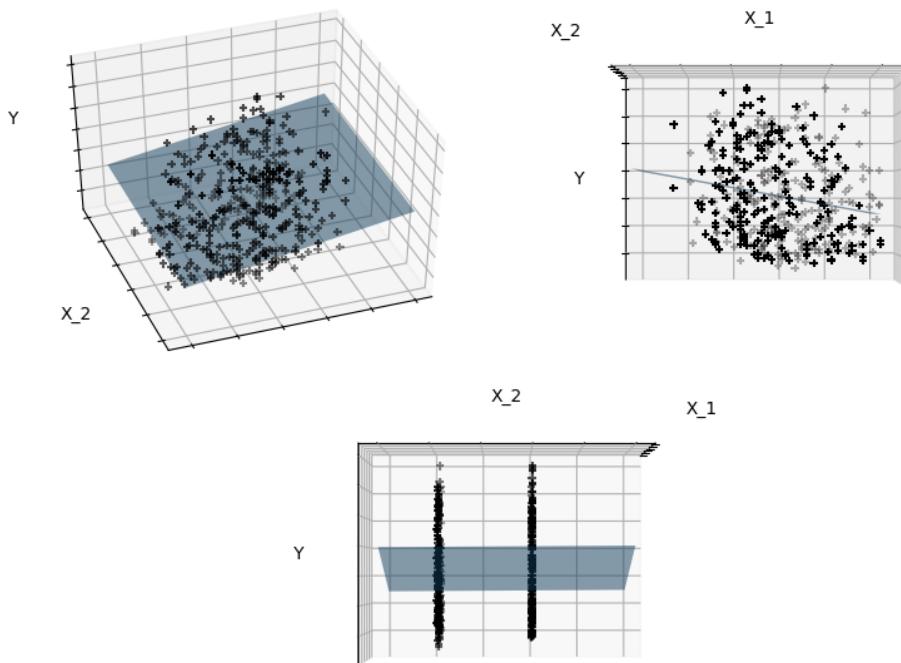

---

**Note:** Capturing in the fitted parameters noise that prevents the model to generalize to new data is called [overfitting](#). The bias introduced by the ridge regression is called a [regularization](#).

---

## Sparsity

### Fitting only features 1 and 2

---

**Note:** A representation of the full diabetes dataset would involve 11 dimensions (10 feature dimensions and one of the target variable). It is hard to develop an intuition on such representation, but it may be useful to keep in mind that it would be a fairly *empty* space.

---

We can see that, although feature 2 has a strong coefficient on the full model, it conveys little information on  $y$  when considered with feature 1.

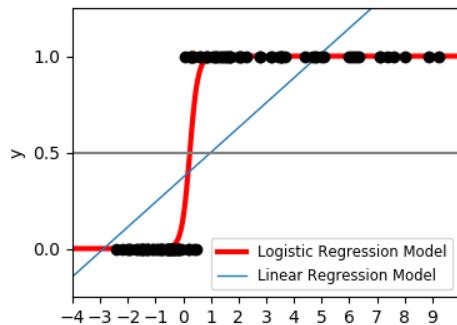

To improve the conditioning of the problem (i.e. mitigating the [The curse of dimensionality](#)), it would be interesting to select only the informative features and set non-informative ones, like feature 2 to 0. Ridge regression will decrease their contribution, but not set them to zero. Another penalization approach, called [Lasso](#) (least absolute shrinkage and selection operator), can set some coefficients to zero. Such methods are called **sparse method** and sparsity can be seen as an application of Occam's razor: *prefer simpler models*.

```
>>> regr = linear_model.Lasso()
>>> scores = [regr.set_params(alpha=alpha
...             ).fit(diabetes_X_train, diabetes_y_train
...             ).score(diabetes_X_test, diabetes_y_test)
...             for alpha in alphas]
>>> best_alpha = alphas[scores.index(max(scores))]
>>> regr.alpha = best_alpha
>>> regr.fit(diabetes_X_train, diabetes_y_train)
Lasso(alpha=0.025118864315095794, copy_X=True, fit_intercept=True,
      max_iter=1000, normalize=False, positive=False, precompute=False,
      random_state=None, selection='cyclic', tol=0.0001, warm_start=False)
>>> print(regr.coef_)
[ 0.          -212.43764548   517.19478111   313.77959962 -160.8303982    -0.
 -187.19554705    69.38229038   508.66011217    71.84239008]
```

### Different algorithms for the same problem

Different algorithms can be used to solve the same mathematical problem. For instance the `Lasso` object in scikit-learn solves the lasso regression problem using a `coordinate descent` method, that is efficient on large datasets. However, scikit-learn also provides the `LassoLars` object using the *LARS* algorithm, which is very efficient for problems in which the weight vector estimated is very sparse (i.e. problems with very few observations).

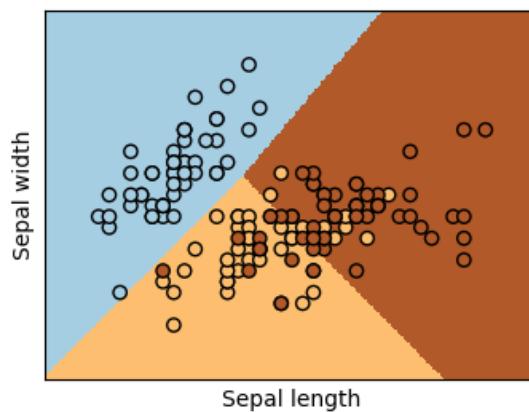

## Classification

For classification, as in the labeling `iris` task, linear regression is not the right approach as it will give too much weight to data far from the decision frontier. A linear approach is to fit a sigmoid function or **logistic** function:

$$y = \text{sigmoid}(X\beta - \text{offset}) + \epsilon = \frac{1}{1 + \exp(-X\beta + \text{offset})} + \epsilon$$

```
>>> logistic = linear_model.LogisticRegression(C=1e5)
>>> logistic.fit(iris_X_train, iris_y_train)
LogisticRegression(C=100000.0, class_weight=None, dual=False,
    fit_intercept=True, intercept_scaling=1, max_iter=100,
    multi_class='ovr', n_jobs=1, penalty='l2', random_state=None,
    solver='liblinear', tol=0.0001, verbose=0, warm_start=False)
```

This is known as `LogisticRegression`.

## Multiclass classification

If you have several classes to predict, an option often used is to fit one-versus-all classifiers and then use a voting heuristic for the final decision.

## Shrinkage and sparsity with logistic regression

The `C` parameter controls the amount of regularization in the `LogisticRegression` object: a large value for `C` results in less regularization. `penalty="l2"` gives *Shrinkage* (i.e. non-sparse coefficients), while `penalty="l1"` gives *Sparsity*.

## Exercise

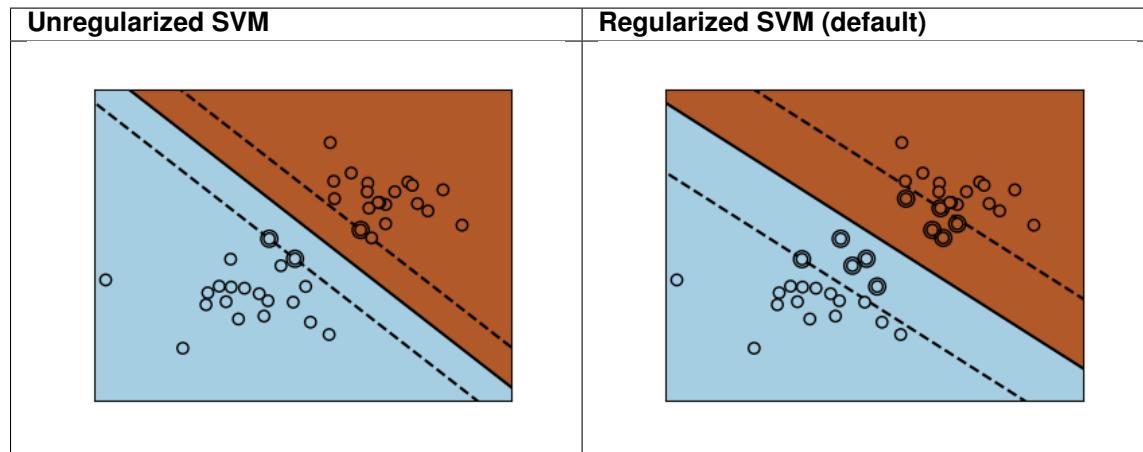

Try classifying the digits dataset with nearest neighbors and a linear model. Leave out the last 10% and test prediction performance on these observations.

Solution: `.../.../auto_examples/exercises/digits_classification_exercise.py`

## Support vector machines (SVMs)

### Linear SVMs

*Support Vector Machines* belong to the discriminant model family: they try to find a combination of samples to build a plane maximizing the margin between the two classes. Regularization is set by the `C` parameter: a small value for `C` means the margin is calculated using many or all of the observations around the separating line (more regularization); a large value for `C` means the margin is calculated on observations close to the separating line (less regularization).

### Example:

- Plot different SVM classifiers in the `iris` dataset

SVMs can be used in regression –`SVR` (Support Vector Regression)–, or in classification –`SVC` (Support Vector Classification).

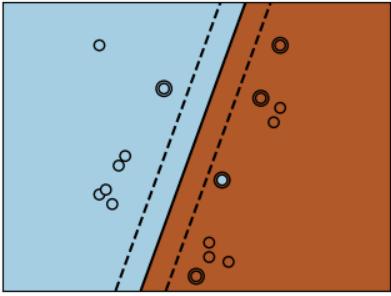

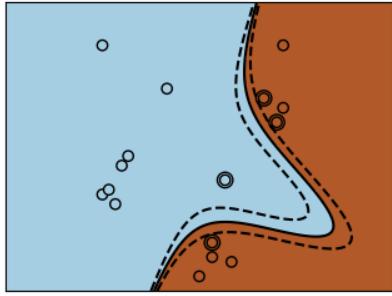

```
>>> from sklearn import svm
>>> svc = svm.SVC(kernel='linear')
>>> svc.fit(iris_X_train, iris_y_train)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='linear',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)
```

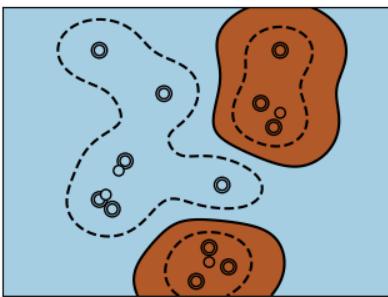

**Warning: Normalizing data**

For many estimators, including the SVMs, having datasets with unit standard deviation for each feature is important to get good prediction.

**Using kernels**

Classes are not always linearly separable in feature space. The solution is to build a decision function that is not linear but may be polynomial instead. This is done using the *kernel trick* that can be seen as creating a decision energy by positioning *kernels* on observations:

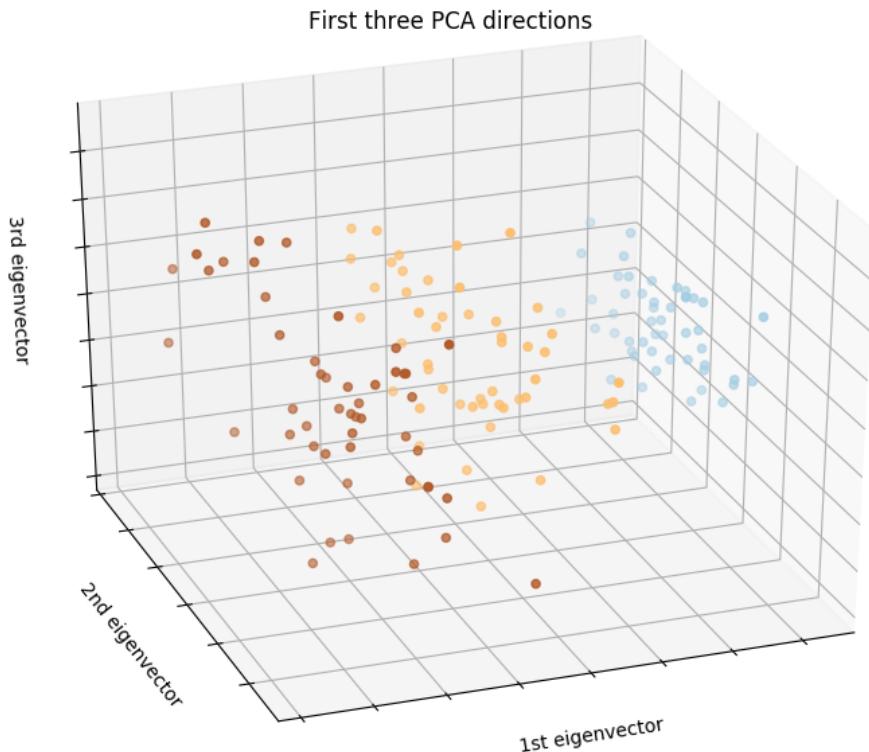

Linear kernel	Polynomial kernel
	
<pre>&gt;&gt;&gt; svc = svm.SVC(kernel='linear')</pre>	<pre>&gt;&gt;&gt; svc = svm.SVC(kernel='poly', ...                  degree=3) &gt;&gt;&gt; # degree: polynomial degree</pre>

**RBF kernel (Radial Basis Function)**

```
>>> svc = svm.SVC(kernel='rbf')
>>> # gamma: inverse of size of
>>> # radial kernel
```

**Interactive example**

See the [SVM GUI](#) to download `svm_gui.py`; add data points of both classes with right and left button, fit the model and change parameters and data.

**Exercise**

Try classifying classes 1 and 2 from the iris dataset with SVMs, with the 2 first features. Leave out 10% of each class and test prediction performance on these observations.

**Warning:** the classes are ordered, do not leave out the last 10%, you would be testing on only one class.

**Hint:** You can use the `decision_function` method on a grid to get intuitions.

```
iris = datasets.load_iris()
X = iris.data
y = iris.target

X = X[y != 0, :2]
y = y[y != 0]
```

Solution: `.../auto_examples/exercises/plot_iris_exercise.py`

## 2.2.3 Model selection: choosing estimators and their parameters

### Score, and cross-validated scores

As we have seen, every estimator exposes a `score` method that can judge the quality of the fit (or the prediction) on new data. **Bigger is better**.

```
>>> from sklearn import datasets, svm
>>> digits = datasets.load_digits()
>>> X_digits = digits.data
>>> y_digits = digits.target
>>> svc = svm.SVC(C=1, kernel='linear')
>>> svc.fit(X_digits[:-100], y_digits[:-100]).score(X_digits[-100:], y_digits[-100:])
0.9799999999999998
```

To get a better measure of prediction accuracy (which we can use as a proxy for goodness of fit of the model), we can successively split the data in *folds* that we use for training and testing:

```
>>> import numpy as np
>>> X_folds = np.array_split(X_digits, 3)
>>> y_folds = np.array_split(y_digits, 3)
>>> scores = list()
>>> for k in range(3):
...     # We use 'list' to copy, in order to 'pop' later on
...     X_train = list(X_folds)
...     X_test = X_train.pop(k)
...     X_train = np.concatenate(X_train)
...     y_train = list(y_folds)
...     y_test = y_train.pop(k)
...     y_train = np.concatenate(y_train)
...     scores.append(svc.fit(X_train, y_train).score(X_test, y_test))
>>> print(scores)
[0.93489148580968284, 0.95659432387312182, 0.93989983305509184]
```

This is called a *KFold* cross-validation.

### Cross-validation generators

Scikit-learn has a collection of classes which can be used to generate lists of train/test indices for popular cross-validation strategies.

They expose a `split` method which accepts the input dataset to be split and yields the train/test set indices for each iteration of the chosen cross-validation strategy.

This example shows an example usage of the `split` method.

```
>>> from sklearn.model_selection import KFold, cross_val_score
>>> X = ["a", "a", "b", "c", "c", "c"]
>>> k_fold = KFold(n_splits=3)
>>> for train_indices, test_indices in k_fold.split(X):
...     print('Train: %s | test: %s' % (train_indices, test_indices))
Train: [2 3 4 5] | test: [0 1]
Train: [0 1 4 5] | test: [2 3]
Train: [0 1 2 3] | test: [4 5]
```

The cross-validation can then be performed easily:

```
>>> [svc.fit(X_digits[train], y_digits[train]).score(X_digits[test], y_digits[test])
...     for train, test in k_fold.split(X_digits)]
[0.93489148580968284, 0.95659432387312182, 0.93989983305509184]
```

The cross-validation score can be directly calculated using the `cross_val_score` helper. Given an estimator, the cross-validation object and the input dataset, the `cross_val_score` splits the data repeatedly into a training and a testing set, trains the estimator using the training set and computes the scores based on the testing set for each iteration of cross-validation.

By default the estimator's `score` method is used to compute the individual scores.

Refer the [metrics module](#) to learn more on the available scoring methods.

```
>>> cross_val_score(svc, X_digits, y_digits, cv=k_fold, n_jobs=-1)
array([ 0.93489149,  0.95659432,  0.93989983])
```

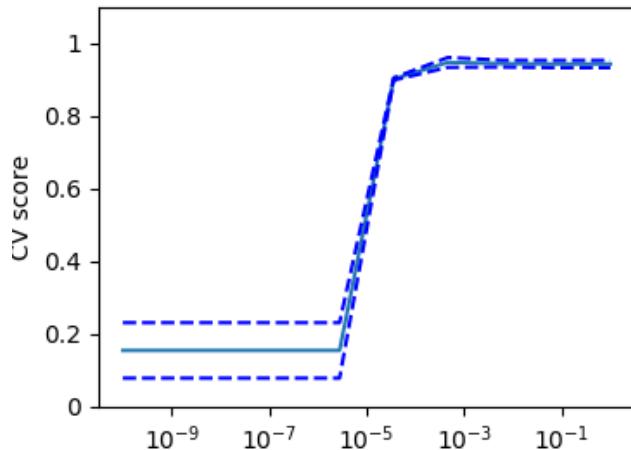

`n_jobs=-1` means that the computation will be dispatched on all the CPUs of the computer.

Alternatively, the `scoring` argument can be provided to specify an alternative scoring method.

```
>>> cross_val_score(svc, X_digits, y_digits, cv=k_fold,
...                   scoring='precision_macro')
array([ 0.93969761,  0.95911415,  0.94041254])
```

### Cross-validation generators

<code>KFold (n_splits, shuffle, random_state)</code>	<code>StratifiedKFold (n_splits, shuffle, random_state)</code>	<code>GroupKFold (n_splits)</code>
Splits it into K folds, trains on K-1 and then tests on the left-out.	Same as K-Fold but preserves the class distribution within each fold.	Ensures that the same group is not in both testing and training sets.
<code>ShuffleSplit (n_splits, test_size, train_size, random_state)</code>	<code>StratifiedShuffleSplit</code>	<code>GroupShuffleSplit</code>
Generates train/test indices based on random permutation.	Same as shuffle split but preserves the class distribution within each iteration.	Ensures that the same group is not in both testing and training sets.
<code>LeaveOneGroupOut ()</code>	<code>LeavePGroupsOut (n_groups)</code>	<code>LeaveOneOut ()</code>
Takes a group array to group observations.	Leave P groups out.	Leave one observation out.
<code>LeavePOut (p)</code>	<code>PredefinedSplit</code>	
Leave P observations out.	Generates train/test indices based on predefined splits.	

**Exercise**

On the digits dataset, plot the cross-validation score of a `SVC` estimator with a linear kernel as a function of parameter  $C$  (use a logarithmic grid of points, from 1 to 10).

```
import numpy as np
from sklearn.model_selection import cross_val_score
from sklearn import datasets, svm

digits = datasets.load_digits()
X = digits.data
y = digits.target

svc = svm.SVC(kernel='linear')
Cs = np.logspace(-10, 0, 10)
```

**Solution:** *Cross-validation on Digits Dataset Exercise*

**Grid-search and cross-validated estimators****Grid-search**

scikit-learn provides an object that, given data, computes the score during the fit of an estimator on a parameter grid and chooses the parameters to maximize the cross-validation score. This object takes an estimator during the construction and exposes an estimator API:

```
>>> from sklearn.model_selection import GridSearchCV, cross_val_score
>>> Cs = np.logspace(-6, -1, 10)
>>> clf = GridSearchCV(estimator=svc, param_grid=dict(C=Cs),
...                     n_jobs=-1)
>>> clf.fit(X_digits[:1000], y_digits[:1000])
GridSearchCV(cv=None, ...
>>> clf.best_score_
0.925...
>>> clf.best_estimator_.C
0.0077...
```

```
>>> # Prediction performance on test set is not as good as on train set
>>> clf.score(X_digits[1000:], y_digits[1000:])
0.943...
```

By default, the `GridSearchCV` uses a 3-fold cross-validation. However, if it detects that a classifier is passed, rather than a regressor, it uses a stratified 3-fold.

### Nested cross-validation

```
>>> cross_val_score(clf, X_digits, y_digits)
...
array([ 0.938...,  0.963...,  0.944...])
```

Two cross-validation loops are performed in parallel: one by the `GridSearchCV` estimator to set gamma and the other one by `cross_val_score` to measure the prediction performance of the estimator. The resulting scores are unbiased estimates of the prediction score on new data.

**Warning:** You cannot nest objects with parallel computing (`n_jobs` different than 1).

### Cross-validated estimators

Cross-validation to set a parameter can be done more efficiently on an algorithm-by-algorithm basis. This is why, for certain estimators, scikit-learn exposes `Cross-validation: evaluating estimator performance` estimators that set their parameter automatically by cross-validation:

```
>>> from sklearn import linear_model, datasets
>>> lasso = linear_model.LassoCV()
>>> diabetes = datasets.load_diabetes()
>>> X_diabetes = diabetes.data
>>> y_diabetes = diabetes.target
>>> lasso.fit(X_diabetes, y_diabetes)
LassoCV(alphas=None, copy_X=True, cv=None, eps=0.001, fit_intercept=True,
        max_iter=1000, n_alphas=100, n_jobs=1, normalize=False, positive=False,
        precompute='auto', random_state=None, selection='cyclic', tol=0.0001,
        verbose=False)
>>> # The estimator chose automatically its lambda:
>>> lasso.alpha_
0.01229...
```

These estimators are called similarly to their counterparts, with ‘CV’ appended to their name.

### Exercise

On the diabetes dataset, find the optimal regularization parameter alpha.

**Bonus:** How much can you trust the selection of alpha?

```
from sklearn import datasets
from sklearn.linear_model import LassoCV
from sklearn.linear_model import Lasso
from sklearn.model_selection import KFold
from sklearn.model_selection import GridSearchCV

diabetes = datasets.load_diabetes()
```

**Solution:** *Cross-validation on diabetes Dataset Exercise*

## 2.2.4 Unsupervised learning: seeking representations of the data

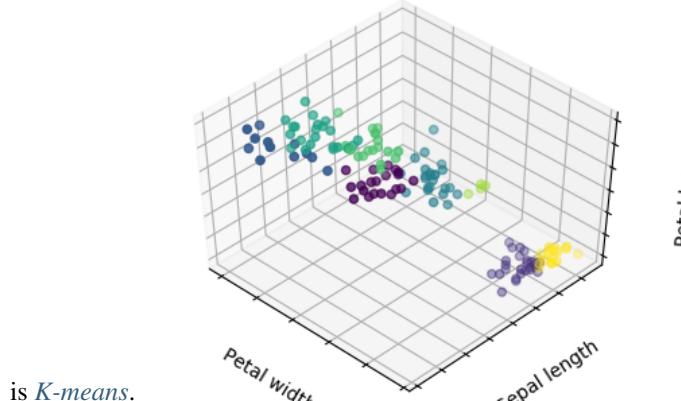

### Clustering: grouping observations together

#### The problem solved in clustering

Given the iris dataset, if we knew that there were 3 types of iris, but did not have access to a taxonomist to label them: we could try a **clustering task**: split the observations into well-separated group called *clusters*.

### K-means clustering

Note that there exist a lot of different clustering criteria and associated algorithms. The simplest clustering algorithm

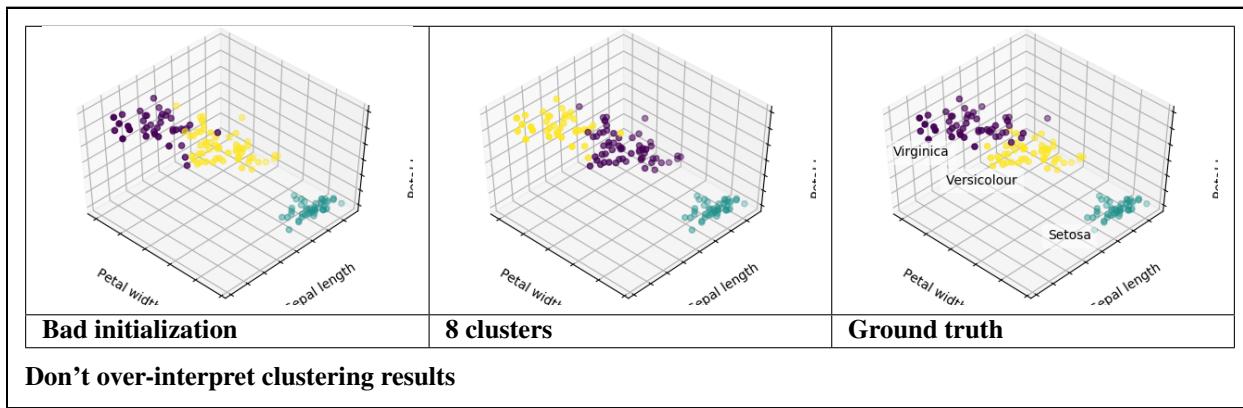

is *K-means*.

```
>>> from sklearn import cluster, datasets
>>> iris = datasets.load_iris()
>>> X_iris = iris.data
>>> y_iris = iris.target

>>> k_means = cluster.KMeans(n_clusters=3)
>>> k_means.fit(X_iris)
KMeans(algorithm='auto', copy_x=True, init='k-means++', ...
>>> print(k_means.labels_[:10])
[1 1 1 1 1 0 0 0 0 2 2 2 2]
>>> print(y_iris[:10])
[0 0 0 0 1 1 1 1 2 2 2 2]
```

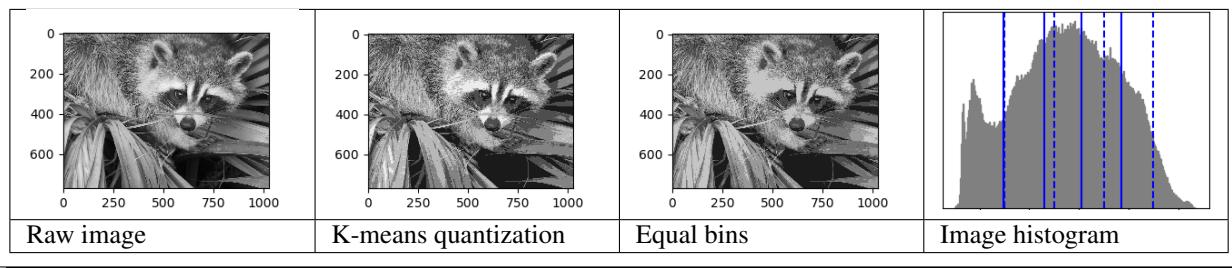

**Warning:** There is absolutely no guarantee of recovering a ground truth. First, choosing the right number of clusters is hard. Second, the algorithm is sensitive to initialization, and can fall into local minima, although scikit-learn employs several tricks to mitigate this issue.

### Application example: vector quantization

Clustering in general and KMeans, in particular, can be seen as a way of choosing a small number of exemplars to compress the information. The problem is sometimes known as [vector quantization](#). For instance, this can be used to posterize an image:

```
>>> import scipy as sp
>>> try:
...     face = sp.face(gray=True)
... except AttributeError:
...     from scipy import misc
...     face = misc.face(gray=True)
>>> X = face.reshape((-1, 1)) # We need an (n_sample, n_feature) array
>>> k_means = cluster.KMeans(n_clusters=5, n_init=1)
>>> k_means.fit(X)
KMeans(algorithm='auto', copy_x=True, init='k-means++', ...
>>> values = k_means.cluster_centers_.squeeze()
>>> labels = k_means.labels_
>>> face_compressed = np.choose(labels, values)
>>> face_compressed.shape = face.shape
```

### Hierarchical agglomerative clustering: Ward

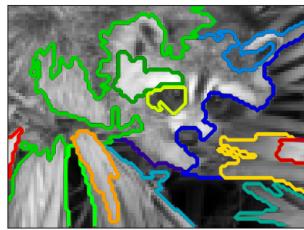

A [Hierarchical clustering](#) method is a type of cluster analysis that aims to build a hierarchy of clusters. In general, the various approaches of this technique are either:

- **Agglomerative** - bottom-up approaches: each observation starts in its own cluster, and clusters are iteratively merged in such a way to minimize a *linkage* criterion. This approach is particularly interesting when the clusters of interest are made of only a few observations. When the number of clusters is large, it is much more computationally efficient than k-means.

- **Divisive** - top-down approaches: all observations start in one cluster, which is iteratively split as one moves down the hierarchy. For estimating large numbers of clusters, this approach is both slow (due to all observations starting as one cluster, which it splits recursively) and statistically ill-posed.

## Connectivity-constrained clustering

With agglomerative clustering, it is possible to specify which samples can be clustered together by giving a connectivity graph. Graphs in the scikit are represented by their adjacency matrix. Often, a sparse matrix is used. This can be useful, for instance, to retrieve connected regions (sometimes also referred to as connected components) when

clustering an image:

```
import matplotlib.pyplot as plt

from sklearn.feature_extraction.image import grid_to_graph
from sklearn.cluster import AgglomerativeClustering

#####
# Generate data
try:  # SciPy >= 0.16 have face in misc
    from scipy.misc import face
    face = face(gray=True)
except ImportError:
    face = sp.face(gray=True)

# Resize it to 10% of the original size to speed up the processing
face = sp.misc.imresize(face, 0.10) / 255.

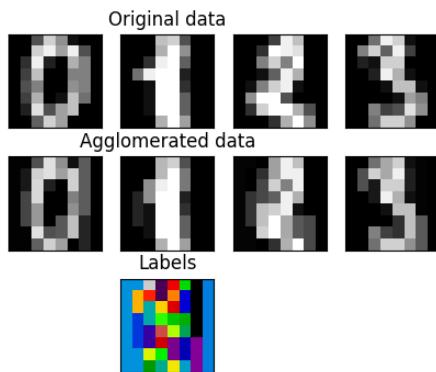

X = np.reshape(face, (-1, 1))

#####
# Define the structure A of the data. Pixels connected to their neighbors.
connectivity = grid_to_graph(*face.shape)

#####
```

## Feature agglomeration

We have seen that sparsity could be used to mitigate the curse of dimensionality, *i.e* an insufficient amount of observations compared to the number of features. Another approach is to merge together similar features: **feature agglomeration**. This approach can be implemented by clustering in the feature direction, in other words clustering

the transposed data.

```
>>> digits = datasets.load_digits()
>>> images = digits.images
>>> X = np.reshape(images, (len(images), -1))
>>> connectivity = grid_to_graph(*images[0].shape)

>>> agglo = cluster.FeatureAgglomeration(connectivity=connectivity,
...                                         n_clusters=32)
>>> agglo.fit(X)
FeatureAgglomeration(affinity='euclidean', compute_full_tree='auto',...
>>> X_reduced = agglo.transform(X)

>>> X_approx = agglo.inverse_transform(X_reduced)
>>> images_approx = np.reshape(X_approx, images.shape)
```

#### **transform and inverse\_transform methods**

Some estimators expose a `transform` method, for instance to reduce the dimensionality of the dataset.

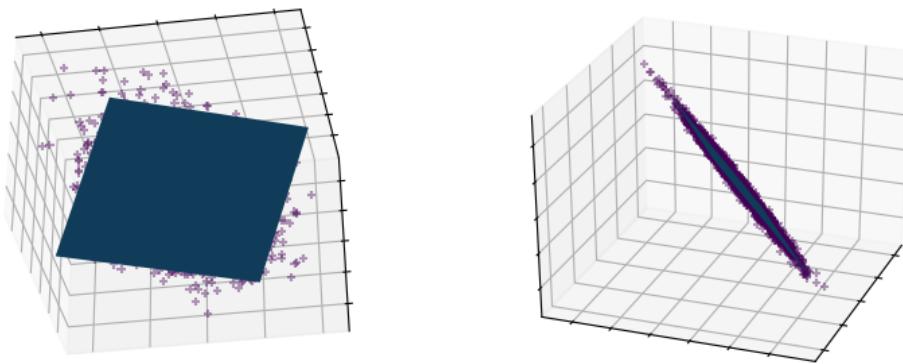

## Decompositions: from a signal to components and loadings

### Components and loadings

If  $X$  is our multivariate data, then the problem that we are trying to solve is to rewrite it on a different observational basis: we want to learn loadings  $L$  and a set of components  $C$  such that  $X = L C$ . Different criteria exist to choose the components

### Principal component analysis: PCA

*Principal component analysis (PCA)* selects the successive components that explain the maximum variance in the signal.

The point cloud spanned by the observations above is very flat in one direction: one of the three univariate features can almost be exactly computed using the other two. PCA finds the directions in which the data is not *flat*

When used to *transform* data, PCA can reduce the dimensionality of the data by projecting on a principal subspace.

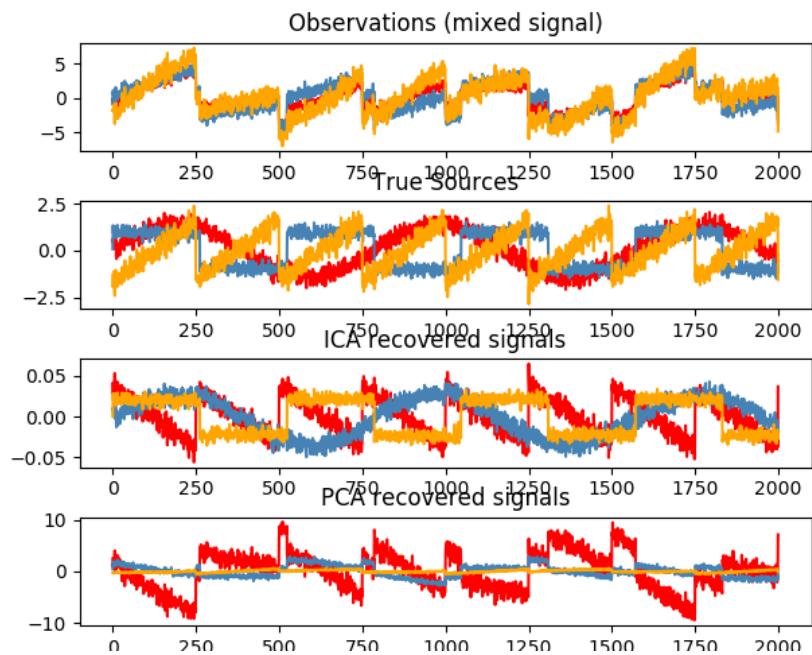

```
>>> # Create a signal with only 2 useful dimensions
>>> x1 = np.random.normal(size=100)
>>> x2 = np.random.normal(size=100)
>>> x3 = x1 + x2
>>> X = np.c_[x1, x2, x3]

>>> from sklearn import decomposition
>>> pca = decomposition.PCA()
>>> pca.fit(X)
PCA(copy=True, iterated_power='auto', n_components=None, random_state=None,
     svd_solver='auto', tol=0.0, whiten=False)
>>> print(pca.explained_variance_)
[ 2.18565811e+00   1.19346747e+00   8.43026679e-32]

>>> # As we can see, only the 2 first components are useful
>>> pca.n_components = 2
>>> X_reduced = pca.fit_transform(X)
>>> X_reduced.shape
(100, 2)
```

## Independent Component Analysis: ICA

*Independent component analysis (ICA)* selects components so that the distribution of their loadings carries a maximum amount of independent information. It is able to recover **non-Gaussian** independent signals:

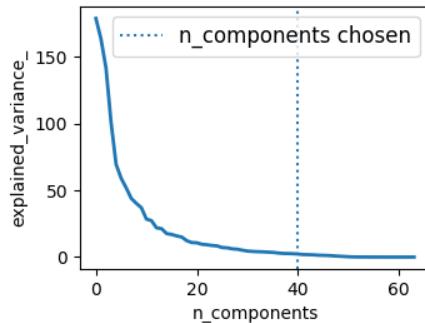

```
>>> # Generate sample data
>>> time = np.linspace(0, 10, 2000)
>>> s1 = np.sin(2 * time) # Signal 1 : sinusoidal signal
>>> s2 = np.sign(np.sin(3 * time)) # Signal 2 : square signal
>>> S = np.c_[s1, s2]
>>> S += 0.2 * np.random.normal(size=S.shape) # Add noise
>>> S /= S.std(axis=0) # Standardize data
>>> # Mix data
>>> A = np.array([[1, 1], [0.5, 2]]) # Mixing matrix
>>> X = np.dot(S, A.T) # Generate observations

>>> # Compute ICA
>>> ica = decomposition.FastICA()
>>> S_ = ica.fit_transform(X) # Get the estimated sources
>>> A_ = ica.mixing_.T
>>> np.allclose(X, np.dot(S_, A_) + ica.mean_)
True
```

## 2.2.5 Putting it all together

### Pipelining

We have seen that some estimators can transform data and that some estimators can predict variables. We can also

create combined estimators:

```
from sklearn import linear_model, decomposition, datasets
from sklearn.pipeline import Pipeline
from sklearn.model_selection import GridSearchCV

logistic = linear_model.LogisticRegression()

pca = decomposition.PCA()
pipe = Pipeline(steps=[('pca', pca), ('logistic', logistic)])

digits = datasets.load_digits()
X_digits = digits.data
y_digits = digits.target

# Plot the PCA spectrum
pca.fit(X_digits)

plt.figure(1, figsize=(4, 3))
plt.clf()
plt.axes([.2, .2, .7, .7])
plt.plot(pca.explained_variance_, linewidth=2)
plt.axis('tight')
plt.xlabel('n_components')
plt.ylabel('explained_variance_')

# Prediction
n_components = [20, 40, 64]
Cs = np.logspace(-4, 4, 3)

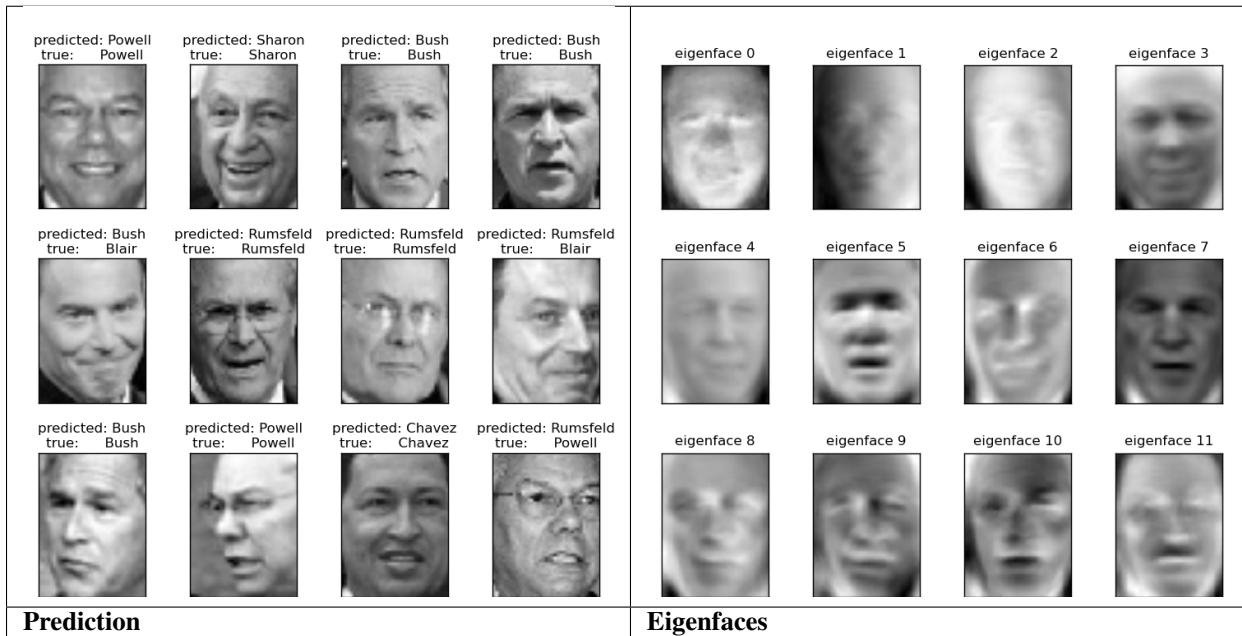

# Parameters of pipelines can be set using '__' separated parameter names:
estimator = GridSearchCV(pipe,
                         dict(pca_n_components=n_components,
                               logistic_C=Cs))
estimator.fit(X_digits, y_digits)

plt.axvline(estimator.best_estimator_.named_steps['pca'].n_components,
            linestyle=':', label='n_components chosen')
plt.legend(prop=dict(size=12))
plt.show()
```

## Face recognition with eigenfaces

The dataset used in this example is a preprocessed excerpt of the “Labeled Faces in the Wild”, also known as LFW:

<http://vis-www.cs.umass.edu/lfw/lfw-funneled.tgz> (233MB)

Expected results for the top 5 most represented people in the dataset:

	precision	recall	f1-score	support
Gerhard_Schroeder	0.91	0.75	0.82	28
Donald_Rumsfeld	0.84	0.82	0.83	33
Tony_Blair	0.65	0.82	0.73	34
Colin_Powell	0.78	0.88	0.83	58
George_W_Bush	0.93	0.86	0.90	129
avg / total	0.86	0.84	0.85	282

## Open problem: Stock Market Structure

Can we predict the variation in stock prices for Google over a given time frame?

*Learning a graph structure*

### 2.2.6 Finding help

#### The project mailing list

If you encounter a bug with scikit-learn or something that needs clarification in the docstring or the online documentation, please feel free to ask on the [Mailing List](#)

## Q&A communities with Machine Learning practitioners

**Quora.com** Quora has a topic for Machine Learning related questions that also features some interesting discussions: <https://www.quora.com/topic/Machine-Learning>

**Stack Exchange** The Stack Exchange family of sites hosts multiple subdomains for Machine Learning questions.

– ‘An excellent free online course for Machine Learning taught by Professor Andrew Ng of Stanford’: <https://www.coursera.org/learn/machine-learning>

– ‘Another excellent free online course that takes a more general approach to Artificial Intelligence’: <https://www.udacity.com/course/intro-to-artificial-intelligence--cs271>

## 2.3 Working With Text Data

The goal of this guide is to explore some of the main scikit-learn tools on a single practical task: analysing a collection of text documents (newsgroups posts) on twenty different topics.

In this section we will see how to:

- load the file contents and the categories
- extract feature vectors suitable for machine learning
- train a linear model to perform categorization
- use a grid search strategy to find a good configuration of both the feature extraction components and the classifier

### 2.3.1 Tutorial setup

To get started with this tutorial, you firstly must have the *scikit-learn* and all of its required dependencies installed.

Please refer to the *installation instructions* page for more information and for per-system instructions.

The source of this tutorial can be found within your scikit-learn folder:

```
scikit-learn/doc/tutorial/text_analytics/
```

The tutorial folder, should contain the following folders:

- \*.rst files - the source of the tutorial document written with sphinx
- data - folder to put the datasets used during the tutorial
- skeletons - sample incomplete scripts for the exercises
- solutions - solutions of the exercises

You can already copy the skeletons into a new folder somewhere on your hard-drive named `sklearn_tut_workspace` where you will edit your own files for the exercises while keeping the original skeletons intact:

```
% cp -r skeletons work_directory/sklearn_tut_workspace
```

Machine Learning algorithms need data. Go to each `$TUTORIAL_HOME/data` sub-folder and run the `fetch_data.py` script from there (after having read them first).

For instance:

```
% cd $TUTORIAL_HOME/data/languages
% less fetch_data.py
% python fetch_data.py
```

### 2.3.2 Loading the 20 newsgroups dataset

The dataset is called “Twenty Newsgroups”. Here is the official description, quoted from the [website](#):

The 20 Newsgroups data set is a collection of approximately 20,000 newsgroup documents, partitioned (nearly) evenly across 20 different newsgroups. To the best of our knowledge, it was originally collected by Ken Lang, probably for his paper “Newsweeder: Learning to filter netnews,” though he does not explicitly mention this collection. The 20 newsgroups collection has become a popular data set for experiments in text applications of machine learning techniques, such as text classification and text clustering.

In the following we will use the built-in dataset loader for 20 newsgroups from scikit-learn. Alternatively, it is possible to download the dataset manually from the web-site and use the `sklearn.datasets.load_files` function by pointing it to the `20news-bydate-train` subfolder of the uncompressed archive folder.

In order to get faster execution times for this first example we will work on a partial dataset with only 4 categories out of the 20 available in the dataset:

```
>>> categories = ['alt.atheism', 'soc.religion.christian',
...                 'comp.graphics', 'sci.med']
```

We can now load the list of files matching those categories as follows:

```
>>> from sklearn.datasets import fetch_20newsgroups
>>> twenty_train = fetch_20newsgroups(subset='train',
...           categories=categories, shuffle=True, random_state=42)
```

The returned dataset is a scikit-learn “bunch”: a simple holder object with fields that can be both accessed as python dict keys or object attributes for convenience, for instance the `target_names` holds the list of the requested category names:

```
>>> twenty_train.target_names
['alt.atheism', 'comp.graphics', 'sci.med', 'soc.religion.christian']
```

The files themselves are loaded in memory in the `data` attribute. For reference the filenames are also available:

```
>>> len(twenty_train.data)
2257
>>> len(twenty_train.filenames)
2257
```

Let’s print the first lines of the first loaded file:

```
>>> print("\n".join(twenty_train.data[0].split("\n")[:3]))
From: sd345@city.ac.uk (Michael Collier)
Subject: Converting images to HP LaserJet III?
Nntp-Posting-Host: hampton

>>> print(twenty_train.target_names[twenty_train.target[0]])
comp.graphics
```

Supervised learning algorithms will require a category label for each document in the training set. In this case the category is the name of the newsgroup which also happens to be the name of the folder holding the individual documents.

For speed and space efficiency reasons scikit-learn loads the target attribute as an array of integers that corresponds to the index of the category name in the `target_names` list. The category integer id of each sample is stored in the `target` attribute:

```
>>> twenty_train.target[:10]
array([1, 1, 3, 3, 3, 3, 3, 2, 2, 2])
```

It is possible to get back the category names as follows:

```
>>> for t in twenty_train.target[:10]:
...     print(twenty_train.target_names[t])
...
comp.graphics
comp.graphics
soc.religion.christian
soc.religion.christian
soc.religion.christian
soc.religion.christian
soc.religion.christian
sci.med
sci.med
sci.med
```

You can notice that the samples have been shuffled randomly (with a fixed RNG seed): this is useful if you select only the first samples to quickly train a model and get a first idea of the results before re-training on the complete dataset later.

### 2.3.3 Extracting features from text files

In order to perform machine learning on text documents, we first need to turn the text content into numerical feature vectors.

#### Bags of words

The most intuitive way to do so is the bags of words representation:

1. assign a fixed integer id to each word occurring in any document of the training set (for instance by building a dictionary from words to integer indices).
2. for each document # $i$ , count the number of occurrences of each word  $w$  and store it in  $X[i, j]$  as the value of feature # $j$  where  $j$  is the index of word  $w$  in the dictionary

The bags of words representation implies that `n_features` is the number of distinct words in the corpus: this number is typically larger than 100,000.

If `n_samples == 10000`, storing `X` as a numpy array of type `float32` would require  $10000 \times 100000 \times 4$  bytes = **4GB in RAM** which is barely manageable on today's computers.

Fortunately, **most values in X will be zeros** since for a given document less than a couple thousands of distinct words will be used. For this reason we say that bags of words are typically **high-dimensional sparse datasets**. We can save a lot of memory by only storing the non-zero parts of the feature vectors in memory.

`scipy.sparse` matrices are data structures that do exactly this, and scikit-learn has built-in support for these structures.

## Tokenizing text with scikit-learn

Text preprocessing, tokenizing and filtering of stopwords are included in a high level component that is able to build a dictionary of features and transform documents to feature vectors:

```
>>> from sklearn.feature_extraction.text import CountVectorizer
>>> count_vect = CountVectorizer()
>>> X_train_counts = count_vect.fit_transform(twenty_train.data)
>>> X_train_counts.shape
(2257, 35788)
```

`CountVectorizer` supports counts of N-grams of words or consecutive characters. Once fitted, the vectorizer has built a dictionary of feature indices:

```
>>> count_vect.vocabulary_.get(u'algorithm')
4690
```

The index value of a word in the vocabulary is linked to its frequency in the whole training corpus.

## From occurrences to frequencies

Occurrence count is a good start but there is an issue: longer documents will have higher average count values than shorter documents, even though they might talk about the same topics.

To avoid these potential discrepancies it suffices to divide the number of occurrences of each word in a document by the total number of words in the document: these new features are called `tf` for Term Frequencies.

Another refinement on top of `tf` is to downscale weights for words that occur in many documents in the corpus and are therefore less informative than those that occur only in a smaller portion of the corpus.

This downscaling is called `tf-idf` for “Term Frequency times Inverse Document Frequency”.

Both `tf` and `tf-idf` can be computed as follows:

```
>>> from sklearn.feature_extraction.text import TfidfTransformer
>>> tf_transformer = TfidfTransformer(use_idf=False).fit(X_train_counts)
>>> X_train_tf = tf_transformer.transform(X_train_counts)
>>> X_train_tf.shape
(2257, 35788)
```

In the above example-code, we firstly use the `fit(..)` method to fit our estimator to the data and secondly the `transform(..)` method to transform our count-matrix to a tf-idf representation. These two steps can be combined to achieve the same end result faster by skipping redundant processing. This is done through using the `fit_transform(..)` method as shown below, and as mentioned in the note in the previous section:

```
>>> tfidf_transformer = TfidfTransformer()
>>> X_train_tfidf = tfidf_transformer.fit_transform(X_train_counts)
>>> X_train_tfidf.shape
(2257, 35788)
```

### 2.3.4 Training a classifier

Now that we have our features, we can train a classifier to try to predict the category of a post. Let’s start with a *naïve Bayes* classifier, which provides a nice baseline for this task. scikit-learn includes several variants of this classifier; the one most suitable for word counts is the multinomial variant:

```
>>> from sklearn.naive_bayes import MultinomialNB
>>> clf = MultinomialNB().fit(X_train_tfidf, twenty_train.target)
```

To try to predict the outcome on a new document we need to extract the features using almost the same feature extracting chain as before. The difference is that we call `transform` instead of `fit_transform` on the transformers, since they have already been fit to the training set:

```
>>> docs_new = ['God is love', 'OpenGL on the GPU is fast']
>>> X_new_counts = count_vect.transform(docs_new)
>>> X_new_tfidf = tfidf_transformer.transform(X_new_counts)

>>> predicted = clf.predict(X_new_tfidf)

>>> for doc, category in zip(docs_new, predicted):
...     print('%r => %s' % (doc, twenty_train.target_names[category]))
...
'God is love' => soc.religion.christian
'OpenGL on the GPU is fast' => comp.graphics
```

## 2.3.5 Building a pipeline

In order to make the vectorizer => transformer => classifier easier to work with, scikit-learn provides a `Pipeline` class that behaves like a compound classifier:

```
>>> from sklearn.pipeline import Pipeline
>>> text_clf = Pipeline([('vect', CountVectorizer()),
...                      ('tfidf', TfidfTransformer()),
...                      ('clf', MultinomialNB()),
...                      ])
```

The names `vect`, `tfidf` and `clf` (classifier) are arbitrary. We shall see their use in the section on grid search, below. We can now train the model with a single command:

```
>>> text_clf.fit(twenty_train.data, twenty_train.target)
Pipeline(...)
```

## 2.3.6 Evaluation of the performance on the test set

Evaluating the predictive accuracy of the model is equally easy:

```
>>> import numpy as np
>>> twenty_test = fetch_20newsgroups(subset='test',
...                                    categories=categories, shuffle=True, random_state=42)
>>> docs_test = twenty_test.data
>>> predicted = text_clf.predict(docs_test)
>>> np.mean(predicted == twenty_test.target)
0.834...
```

I.e., we achieved 83.4% accuracy. Let's see if we can do better with a linear *support vector machine (SVM)*, which is widely regarded as one of the best text classification algorithms (although it's also a bit slower than naïve Bayes). We can change the learner by just plugging a different classifier object into our pipeline:

```
>>> from sklearn.linear_model import SGDClassifier
>>> text_clf = Pipeline([('vect', CountVectorizer()),
```

```

...
        ('tfidf', TfidfTransformer()),
...
        ('clf', SGDClassifier(loss='hinge', penalty='l2',
                               alpha=1e-3, n_iter=5, random_
                               state=42)),
...
    ])
>>> text_clf.fit(twenty_train.data, twenty_train.target)
Pipeline(...)
>>> predicted = text_clf.predict(docs_test)
>>> np.mean(predicted == twenty_test.target)
0.912...

```

scikit-learn further provides utilities for more detailed performance analysis of the results:

```

>>> from sklearn import metrics
>>> print(metrics.classification_report(twenty_test.target, predicted,
...                                         target_names=twenty_test.target_names))
...
              precision    recall   f1-score   support
...
alt.atheism      0.95     0.81     0.87     319
comp.graphics    0.88     0.97     0.92     389
sci.med          0.94     0.90     0.92     396
soc.religion.christian  0.90     0.95     0.93     398
...
avg / total      0.92     0.91     0.91    1502

>>> metrics.confusion_matrix(twenty_test.target, predicted)
array([[258,   11,   15,   35],
       [  4, 379,    3,   31],
       [  5,  33, 355,    3],
       [  5,  10,    4, 379]])

```

As expected the confusion matrix shows that posts from the newsgroups on atheism and christian are more often confused for one another than with computer graphics.

### 2.3.7 Parameter tuning using grid search

We've already encountered some parameters such as `use_idf` in the `TfidfTransformer`. Classifiers tend to have many parameters as well; e.g., `MultinomialNB` includes a smoothing parameter `alpha` and `SGDClassifier` has a penalty parameter `alpha` and configurable loss and penalty terms in the objective function (see the module documentation, or use the Python `help` function, to get a description of these).

Instead of tweaking the parameters of the various components of the chain, it is possible to run an exhaustive search of the best parameters on a grid of possible values. We try out all classifiers on either words or bigrams, with or without `idf`, and with a penalty parameter of either 0.01 or 0.001 for the linear SVM:

```

>>> from sklearn.model_selection import GridSearchCV
>>> parameters = {'vect__ngram_range': [(1, 1), (1, 2)],
...                  'tfidf__use_idf': (True, False),
...                  'clf__alpha': (1e-2, 1e-3),
... }

```

Obviously, such an exhaustive search can be expensive. If we have multiple CPU cores at our disposal, we can tell the grid searcher to try these eight parameter combinations in parallel with the `n_jobs` parameter. If we give this parameter a value of `-1`, grid search will detect how many cores are installed and uses them all:

```
>>> gs_clf = GridSearchCV(text_clf, parameters, n_jobs=-1)
```

The grid search instance behaves like a normal scikit-learn model. Let's perform the search on a smaller subset of the training data to speed up the computation:

```
>>> gs_clf = gs_clf.fit(twenty_train.data[:400], twenty_train.target[:400])
```

The result of calling `fit` on a `GridSearchCV` object is a classifier that we can use to predict:

```
>>> twenty_train.target_names[gs_clf.predict(['God is love'])[0]]  
'soc.religion.christian'
```

The object's `best_score_` and `best_params_` attributes store the best mean score and the parameters setting corresponding to that score:

```
>>> gs_clf.best_score_  
0.900...  
>>> for param_name in sorted(parameters.keys()):  
...     print("%s: %r" % (param_name, gs_clf.best_params_[param_name]))  
...  
clf_alpha: 0.001  
tfidf_use_idf: True  
vect_ngram_range: (1, 1)
```

A more detailed summary of the search is available at `gs_clf.cv_results_`.

The `cv_results_` parameter can be easily imported into pandas as a DataFrame for further inspection.

## Exercises

To do the exercises, copy the content of the ‘skeletons’ folder as a new folder named ‘workspace’:

```
% cp -r skeletons workspace
```

You can then edit the content of the workspace without fear of loosing the original exercise instructions.

Then fire an ipython shell and run the work-in-progress script with:

```
[1] %run workspace/exercise_XX_script.py arg1 arg2 arg3
```

If an exception is triggered, use `%debug` to fire-up a post mortem ipdb session.

Refine the implementation and iterate until the exercise is solved.

**For each exercise, the skeleton file provides all the necessary import statements, boilerplate code to load the data and sample code to evaluate the predictive accuracy of the model.**

### 2.3.8 Exercise 1: Language identification

- Write a text classification pipeline using a custom preprocessor and CharNGramAnalyzer using data from Wikipedia articles as training set.
- Evaluate the performance on some held out test set.

ipython command line:

```
%run workspace/exercise_01_language_train_model.py data/languages/paragraphs/
```

### 2.3.9 Exercise 2: Sentiment Analysis on movie reviews

- Write a text classification pipeline to classify movie reviews as either positive or negative.
- Find a good set of parameters using grid search.
- Evaluate the performance on a held out test set.

ipython command line:

```
%run workspace/exercise_02_sentiment.py data/movie_reviews/txt_sentoken/
```

### 2.3.10 Exercise 3: CLI text classification utility

Using the results of the previous exercises and the `cPickle` module of the standard library, write a command line utility that detects the language of some text provided on `stdin` and estimate the polarity (positive or negative) if the text is written in English.

Bonus point if the utility is able to give a confidence level for its predictions.

### 2.3.11 Where to from here

Here are a few suggestions to help further your scikit-learn intuition upon the completion of this tutorial:

- Try playing around with the `analyzer` and `token` normalisation under [CountVectorizer](#)
- If you don't have labels, try using [Clustering](#) on your problem.
- If you have multiple labels per document, e.g categories, have a look at the [Multiclass and multilabel section](#)
- Try using [Truncated SVD](#) for latent semantic analysis.
- Have a look at using [Out-of-core Classification](#) to learn from data that would not fit into the computer main memory.
- Have a look at the [Hashing Vectorizer](#) as a memory efficient alternative to [CountVectorizer](#).

## 2.4 Choosing the right estimator

Often the hardest part of solving a machine learning problem can be finding the right estimator for the job.

Different estimators are better suited for different types of data and different problems.

The flowchart below is designed to give users a bit of a rough guide on how to approach problems with regard to which estimators to try on your data.

Click on any estimator in the chart below to see its documentation.

## 2.5 External Resources, Videos and Talks

For written tutorials, see the [Tutorial section](#) of the documentation.

## 2.5.1 New to Scientific Python?

For those that are still new to the scientific Python ecosystem, we highly recommend the [Python Scientific Lecture Notes](#). This will help you find your footing a bit and will definitely improve your scikit-learn experience. A basic understanding of NumPy arrays is recommended to make the most of scikit-learn.

## 2.5.2 External Tutorials

There are several online tutorials available which are geared toward specific subject areas:

- [Machine Learning for NeuroImaging in Python](#)
- [Machine Learning for Astronomical Data Analysis](#)

## 2.5.3 Videos

- An introduction to scikit-learn [Part I](#) and [Part II](#) at Scipy 2013 by [Gael Varoquaux](#), [Jake Vanderplas](#) and [Olivier Grisel](#). Notebooks on [github](#).

- [Introduction to scikit-learn](#) by [Gael Varoquaux](#) at ICML 2010

A three minute video from a very early stage of the scikit, explaining the basic idea and approach we are following.

- [Introduction to statistical learning with scikit-learn](#) by [Gael Varoquaux](#) at SciPy 2011

An extensive tutorial, consisting of four sessions of one hour. The tutorial covers the basics of machine learning, many algorithms and how to apply them using scikit-learn. The material corresponding is now in the scikit-learn documentation section [A tutorial on statistical-learning for scientific data processing](#).

- [Statistical Learning for Text Classification with scikit-learn and NLTK](#) (and [slides](#)) by [Olivier Grisel](#) at PyCon 2011

Thirty minute introduction to text classification. Explains how to use NLTK and scikit-learn to solve real-world text classification tasks and compares against cloud-based solutions.

- [Introduction to Interactive Predictive Analytics in Python with scikit-learn](#) by [Olivier Grisel](#) at PyCon 2012

3-hours long introduction to prediction tasks using scikit-learn.

- [scikit-learn - Machine Learning in Python](#) by [Jake Vanderplas](#) at the 2012 PyData workshop at Google

Interactive demonstration of some scikit-learn features. 75 minutes.

- [scikit-learn tutorial](#) by [Jake Vanderplas](#) at PyData NYC 2012

Presentation using the online tutorial, 45 minutes.

---

### Note: Doctest Mode

The code-examples in the above tutorials are written in a *python-console* format. If you wish to easily execute these examples in **IPython**, use:

```
%doctest_mode
```

in the IPython-console. You can then simply copy and paste the examples directly into IPython without having to worry about removing the >>> manually.

---

## 3.1 Supervised learning

### 3.1.1 Generalized Linear Models

The following are a set of methods intended for regression in which the target value is expected to be a linear combination of the input variables. In mathematical notion, if  $\hat{y}$  is the predicted value.

$$\hat{y}(w, x) = w_0 + w_1x_1 + \dots + w_px_p$$

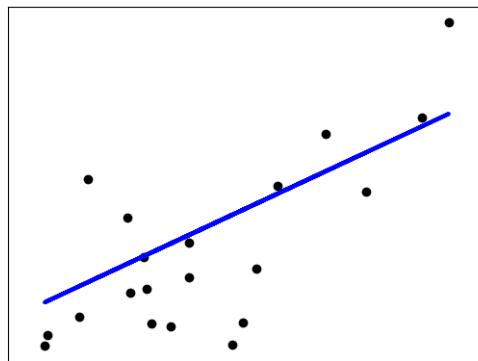

Across the module, we designate the vector  $w = (w_1, \dots, w_p)$  as `coef_` and  $w_0$  as `intercept_`.

To perform classification with generalized linear models, see [Logistic regression](#).

#### Ordinary Least Squares

[LinearRegression](#) fits a linear model with coefficients  $w = (w_1, \dots, w_p)$  to minimize the residual sum of squares between the observed responses in the dataset, and the responses predicted by the linear approximation. Mathematically it solves a problem of the form:

$$\min_w \|Xw - y\|_2^2$$

[LinearRegression](#) will take in its `fit` method arrays `X`, `y` and will store the coefficients `w` of the linear model in its `coef_` member:

```
>>> from sklearn import linear_model
>>> reg = linear_model.LinearRegression()
>>> reg.fit ([[0, 0], [1, 1], [2, 2], [0, 1], [2, 1]])
LinearRegression(copy_X=True, fit_intercept=True, n_jobs=1, normalize=False)
>>> reg.coef_
array([ 0.5,  0.5])
```

However, coefficient estimates for Ordinary Least Squares rely on the independence of the model terms. When terms are correlated and the columns of the design matrix  $X$  have an approximate linear dependence, the design matrix becomes close to singular and as a result, the least-squares estimate becomes highly sensitive to random errors in the observed response, producing a large variance. This situation of *multicollinearity* can arise, for example, when data are collected without an experimental design.

### Examples:

- *Linear Regression Example*

## Ordinary Least Squares Complexity

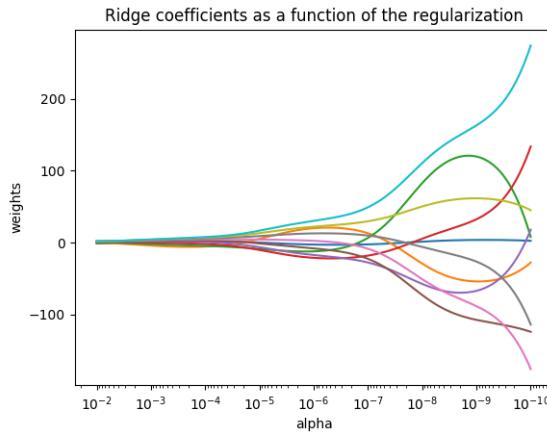

This method computes the least squares solution using a singular value decomposition of  $X$ . If  $X$  is a matrix of size  $(n, p)$  this method has a cost of  $O(np^2)$ , assuming that  $n \geq p$ .

## Ridge Regression

*Ridge* regression addresses some of the problems of *Ordinary Least Squares* by imposing a penalty on the size of coefficients. The ridge coefficients minimize a penalized residual sum of squares,

$$\min_w \|Xw - y\|_2^2 + \alpha \|w\|_2^2$$

Here,  $\alpha \geq 0$  is a complexity parameter that controls the amount of shrinkage: the larger the value of  $\alpha$ , the greater the amount of shrinkage and thus the coefficients become more robust to collinearity.

As with other linear models, *Ridge* will take in its `fit` method arrays  $X$ ,  $y$  and will store the coefficients  $w$  of the linear model in its `coef_` member:

```
>>> from sklearn import linear_model
>>> reg = linear_model.Ridge (alpha = .5)
>>> reg.fit ([[0, 0], [0, 0], [1, 1]], [0, .1, 1])
Ridge(alpha=0.5, copy_X=True, fit_intercept=True, max_iter=None,
      normalize=False, random_state=None, solver='auto', tol=0.001)
>>> reg.coef_
array([ 0.34545455,  0.34545455])
>>> reg.intercept_
0.13636...
```

**Examples:**

- *Plot Ridge coefficients as a function of the regularization*
- *Classification of text documents using sparse features*

**Ridge Complexity**

This method has the same order of complexity than an *Ordinary Least Squares*.

**Setting the regularization parameter: generalized Cross-Validation**

*RidgeCV* implements ridge regression with built-in cross-validation of the alpha parameter. The object works in the same way as GridSearchCV except that it defaults to Generalized Cross-Validation (GCV), an efficient form of leave-one-out cross-validation:

```
>>> from sklearn import linear_model
>>> reg = linear_model.RidgeCV(alphas=[0.1, 1.0, 10.0])
>>> reg.fit([[0, 0], [0, 0], [1, 1]], [0, .1, 1])
RidgeCV(alphas=[0.1, 1.0, 10.0], cv=None, fit_intercept=True, scoring=None,
        normalize=False)
>>> reg.alpha_
0.1
```

**References**

- “Notes on Regularized Least Squares”, Rifkin & Lippert ([technical report](#), [course slides](#)).

**Lasso**

The *Lasso* is a linear model that estimates sparse coefficients. It is useful in some contexts due to its tendency to prefer solutions with fewer parameter values, effectively reducing the number of variables upon which the given solution is dependent. For this reason, the Lasso and its variants are fundamental to the field of compressed sensing. Under certain conditions, it can recover the exact set of non-zero weights (see *Compressive sensing: tomography reconstruction with L1 prior (Lasso)*).

Mathematically, it consists of a linear model trained with  $\ell_1$  prior as regularizer. The objective function to minimize

is:

$$\min_w \frac{1}{2n_{samples}} \|Xw - y\|_2^2 + \alpha \|w\|_1$$

The lasso estimate thus solves the minimization of the least-squares penalty with  $\alpha \|w\|_1$  added, where  $\alpha$  is a constant and  $\|w\|_1$  is the  $\ell_1$ -norm of the parameter vector.

The implementation in the class [Lasso](#) uses coordinate descent as the algorithm to fit the coefficients. See [Least Angle Regression](#) for another implementation:

```
>>> from sklearn import linear_model
>>> reg = linear_model.Lasso(alpha = 0.1)
>>> reg.fit([[0, 0], [1, 1]], [0, 1])
Lasso(alpha=0.1, copy_X=True, fit_intercept=True, max_iter=1000,
      normalize=False, positive=False, precompute=False, random_state=None,
      selection='cyclic', tol=0.0001, warm_start=False)
>>> reg.predict([[1, 1]])
array([ 0.8])
```

Also useful for lower-level tasks is the function [lasso\\_path](#) that computes the coefficients along the full path of possible values.

### Examples:

- [Lasso and Elastic Net for Sparse Signals](#)
- [Compressive sensing: tomography reconstruction with L1 prior \(Lasso\)](#)

---

### Note: Feature selection with Lasso

As the Lasso regression yields sparse models, it can thus be used to perform feature selection, as detailed in [L1-based feature selection](#).

---

---

### Note: Randomized sparsity

For feature selection or sparse recovery, it may be interesting to use [Randomized sparse models](#).

---

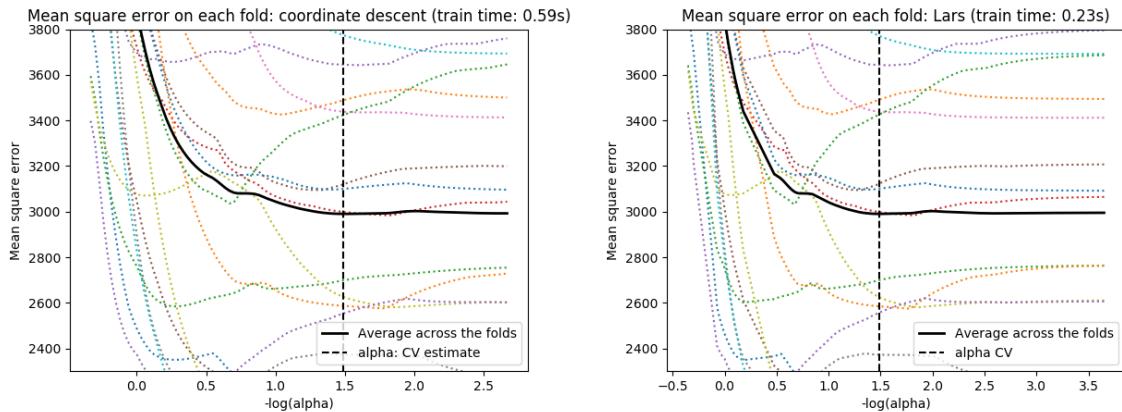

### Setting regularization parameter

The alpha parameter controls the degree of sparsity of the coefficients estimated.

### Using cross-validation

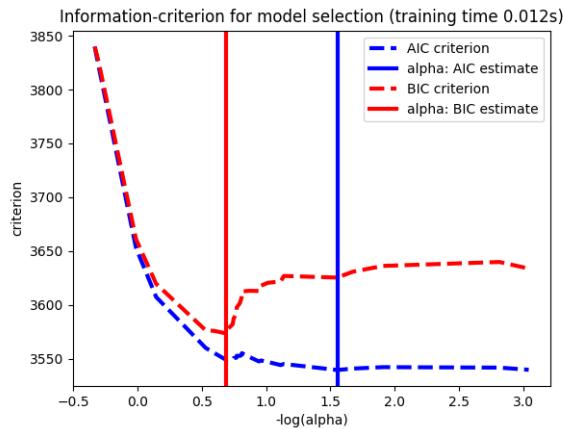

scikit-learn exposes objects that set the Lasso alpha parameter by cross-validation: [LassoCV](#) and [LassoLarsCV](#). [LassoLarsCV](#) is based on the [Least Angle Regression](#) algorithm explained below.

For high-dimensional datasets with many collinear regressors, [LassoCV](#) is most often preferable. However, [LassoLarsCV](#) has the advantage of exploring more relevant values of alpha parameter, and if the number of samples is very small compared to the number of features, it is often faster than [LassoCV](#).

## Information-criteria based model selection

Alternatively, the estimator `LassoLarsIC` proposes to use the Akaike information criterion (AIC) and the Bayes Information criterion (BIC). It is a computationally cheaper alternative to find the optimal value of alpha as the regularization path is computed only once instead of  $k+1$  times when using  $k$ -fold cross-validation. However, such criteria needs a proper estimation of the degrees of freedom of the solution, are derived for large samples (asymptotic results) and assume the model is correct, i.e. that the data are actually generated by this model. They also tend to break when the problem is badly conditioned (more features than samples).

### Examples:

- *Lasso model selection: Cross-Validation / AIC / BIC*

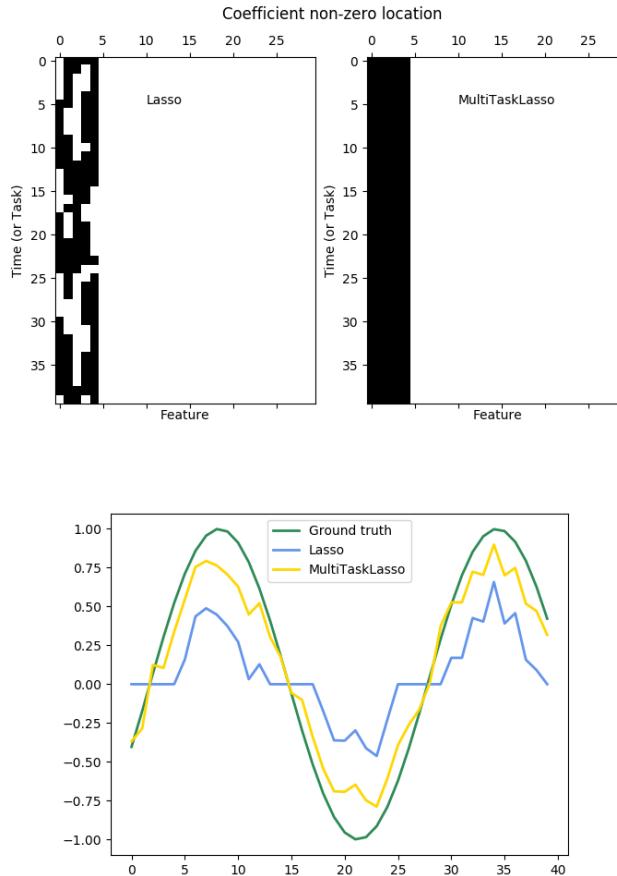

## Comparison with the regularization parameter of SVM

The equivalence between `alpha` and the regularization parameter of SVM, `C` is given by `alpha = 1 / C` or `alpha = 1 / (n_samples * C)`, depending on the estimator and the exact objective function optimized by the model.

## Multi-task Lasso

The `MultiTaskLasso` is a linear model that estimates sparse coefficients for multiple regression problems jointly:  $y$  is a 2D array, of shape  $(n_{samples}, n_{tasks})$ . The constraint is that the selected features are the same for all the regression problems, also called tasks.

The following figure compares the location of the non-zeros in  $W$  obtained with a simple Lasso or a MultiTaskLasso. The Lasso estimates yields scattered non-zeros while the non-zeros of the MultiTaskLasso are full columns.

Fitting a time-series model, imposing that any active feature be active at all times.

### Examples:

- *Joint feature selection with multi-task Lasso*

Mathematically, it consists of a linear model trained with a mixed  $\ell_1 \ell_2$  prior as regularizer. The objective function to minimize is:

$$\min_w \frac{1}{2n_{samples}} \|XW - Y\|_{Fro}^2 + \alpha \|W\|_{21}$$

where  $Fro$  indicates the Frobenius norm:

$$\|A\|_{Fro} = \sqrt{\sum_{ij} a_{ij}^2}$$

and  $\ell_1 \ell_2$  reads:

$$\|A\|_{21} = \sum_i \sqrt{\sum_j a_{ij}^2}$$

The implementation in the class `MultiTaskLasso` uses coordinate descent as the algorithm to fit the coefficients.

## Elastic Net

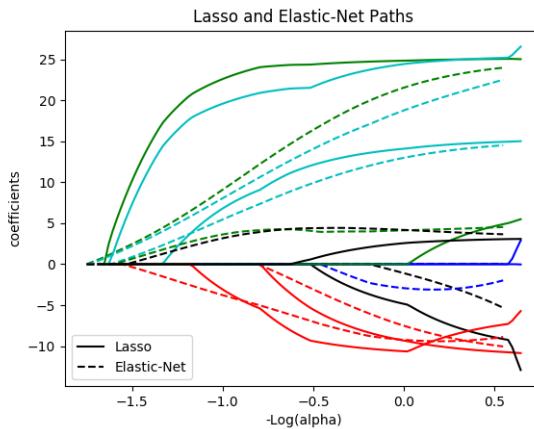

`ElasticNet` is a linear regression model trained with L1 and L2 prior as regularizer. This combination allows for learning a sparse model where few of the weights are non-zero like `Lasso`, while still maintaining the regularization properties of `Ridge`. We control the convex combination of L1 and L2 using the `l1_ratio` parameter.

Elastic-net is useful when there are multiple features which are correlated with one another. Lasso is likely to pick one of these at random, while elastic-net is likely to pick both.

A practical advantage of trading-off between Lasso and Ridge is it allows Elastic-Net to inherit some of Ridge's stability under rotation.

The objective function to minimize is in this case

$$\min_w \frac{1}{2n_{samples}} \|Xw - y\|_2^2 + \alpha\rho\|w\|_1 + \frac{\alpha(1-\rho)}{2}\|w\|_2^2$$

The class `ElasticNetCV` can be used to set the parameters `alpha` ( $\alpha$ ) and `l1_ratio` ( $\rho$ ) by cross-validation.

### Examples:

- `Lasso and Elastic Net for Sparse Signals`
- `Lasso and Elastic Net`

## Multi-task Elastic Net

The `MultiTaskElasticNet` is an elastic-net model that estimates sparse coefficients for multiple regression problems jointly:  $Y$  is a 2D array, of shape `(n_samples, n_tasks)`. The constraint is that the selected features are the same for all the regression problems, also called tasks.

Mathematically, it consists of a linear model trained with a mixed  $\ell_1 \ell_2$  prior and  $\ell_2$  prior as regularizer. The objective function to minimize is:

$$\min_W \frac{1}{2n_{samples}} \|XW - Y\|_{Fro}^2 + \alpha\rho\|W\|_{21} + \frac{\alpha(1-\rho)}{2}\|W\|_{Fro}^2$$

The implementation in the class `MultiTaskElasticNet` uses coordinate descent as the algorithm to fit the coefficients.

The class `MultiTaskElasticNetCV` can be used to set the parameters `alpha` ( $\alpha$ ) and `l1_ratio` ( $\rho$ ) by cross-validation.

## Least Angle Regression

Least-angle regression (LARS) is a regression algorithm for high-dimensional data, developed by Bradley Efron, Trevor Hastie, Iain Johnstone and Robert Tibshirani. LARS is similar to forward stepwise regression. At each step, it finds the predictor most correlated with the response. When there are multiple predictors having equal correlation, instead of continuing along the same predictor, it proceeds in a direction equiangular between the predictors.

The advantages of LARS are:

- It is numerically efficient in contexts where  $p \gg n$  (i.e., when the number of dimensions is significantly greater than the number of points)
- It is computationally just as fast as forward selection and has the same order of complexity as an ordinary least squares.
- It produces a full piecewise linear solution path, which is useful in cross-validation or similar attempts to tune the model.
- If two variables are almost equally correlated with the response, then their coefficients should increase at approximately the same rate. The algorithm thus behaves as intuition would expect, and also is more stable.
- It is easily modified to produce solutions for other estimators, like the Lasso.

The disadvantages of the LARS method include:

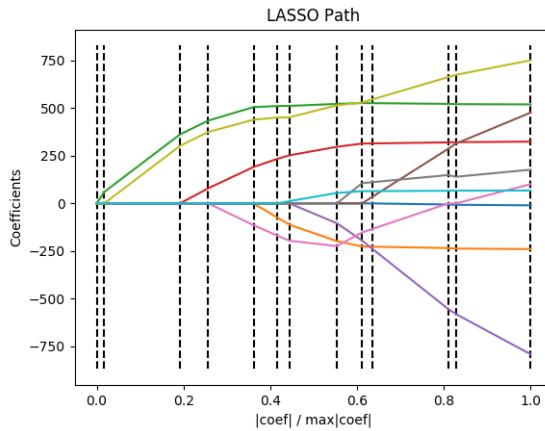

- Because LARS is based upon an iterative refitting of the residuals, it would appear to be especially sensitive to the effects of noise. This problem is discussed in detail by Weisberg in the discussion section of the Efron et al. (2004) Annals of Statistics article.

The LARS model can be used using estimator `Lars`, or its low-level implementation `lars_path`.

## LARS Lasso

`LassoLars` is a lasso model implemented using the LARS algorithm, and unlike the implementation based on coordinate\_descent, this yields the exact solution, which is piecewise linear as a function of the norm of its coefficients.

```
>>> from sklearn import linear_model
>>> reg = linear_model.LassoLars(alpha=.1)
>>> reg.fit([[0, 0], [1, 1], [0, 1]])
LassoLars(alpha=0.1, copy_X=True, eps=..., fit_intercept=True,
          fit_path=True, max_iter=500, normalize=True, positive=False,
          precompute='auto', verbose=False)
>>> reg.coef_
array([ 0.717157...,  0.        ])
```

### Examples:

- [Lasso path using LARS](#)

The Lars algorithm provides the full path of the coefficients along the regularization parameter almost for free, thus a common operation consist of retrieving the path with function `lars_path`

### Mathematical formulation

The algorithm is similar to forward stepwise regression, but instead of including variables at each step, the estimated parameters are increased in a direction equiangular to each one's correlations with the residual.

Instead of giving a vector result, the LARS solution consists of a curve denoting the solution for each value of the L1 norm of the parameter vector. The full coefficients path is stored in the array `coef_path_`, which has size `(n_features, max_features+1)`. The first column is always zero.

### References:

- Original Algorithm is detailed in the paper [Least Angle Regression](#) by Hastie et al.

### Orthogonal Matching Pursuit (OMP)

`OrthogonalMatchingPursuit` and `orthogonal_mp` implements the OMP algorithm for approximating the fit of a linear model with constraints imposed on the number of non-zero coefficients (ie. the  $L_0$  pseudo-norm).

Being a forward feature selection method like [Least Angle Regression](#), orthogonal matching pursuit can approximate the optimum solution vector with a fixed number of non-zero elements:

$$\arg \min ||y - X\gamma||_2^2 \text{ subject to } ||\gamma||_0 \leq n_{nonzero\_coefs}$$

Alternatively, orthogonal matching pursuit can target a specific error instead of a specific number of non-zero coefficients. This can be expressed as:

$$\arg \min ||\gamma||_0 \text{ subject to } ||y - X\gamma||_2^2 \leq \text{tol}$$

OMP is based on a greedy algorithm that includes at each step the atom most highly correlated with the current residual. It is similar to the simpler matching pursuit (MP) method, but better in that at each iteration, the residual is recomputed using an orthogonal projection on the space of the previously chosen dictionary elements.

#### Examples:

- *Orthogonal Matching Pursuit*

## Bayesian Regression

Bayesian regression techniques can be used to include regularization parameters in the estimation procedure: the regularization parameter is not set in a hard sense but tuned to the data at hand.

This can be done by introducing [uninformative priors](#) over the hyper parameters of the model. The  $\ell_2$  regularization used in [Ridge Regression](#) is equivalent to finding a maximum a posteriori estimation under a Gaussian prior over the parameters  $w$  with precision  $\lambda^{-1}$ . Instead of setting *lambda* manually, it is possible to treat it as a random variable to be estimated from the data.

To obtain a fully probabilistic model, the output  $y$  is assumed to be Gaussian distributed around  $Xw$ :

$$p(y|X, w, \alpha) = \mathcal{N}(y|Xw, \alpha)$$

Alpha is again treated as a random variable that is to be estimated from the data.

The advantages of Bayesian Regression are:

- It adapts to the data at hand.
- It can be used to include regularization parameters in the estimation procedure.

The disadvantages of Bayesian regression include:

- Inference of the model can be time consuming.

#### References

- A good introduction to Bayesian methods is given in C. Bishop: Pattern Recognition and Machine learning
- Original Algorithm is detailed in the book *Bayesian learning for neural networks* by Radford M. Neal

## Bayesian Ridge Regression

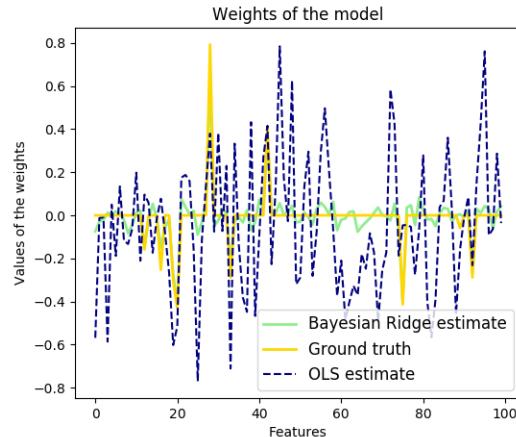

[BayesianRidge](#) estimates a probabilistic model of the regression problem as described above. The prior for the parameter  $w$  is given by a spherical Gaussian:

$$p(w|\lambda) = \mathcal{N}(w|0, \lambda^{-1} \mathbf{I}_p)$$

The priors over  $\alpha$  and  $\lambda$  are chosen to be [gamma distributions](#), the conjugate prior for the precision of the Gaussian.

The resulting model is called *Bayesian Ridge Regression*, and is similar to the classical [Ridge](#). The parameters  $w$ ,  $\alpha$  and  $\lambda$  are estimated jointly during the fit of the model. The remaining hyperparameters are the parameters of the gamma priors over  $\alpha$  and  $\lambda$ . These are usually chosen to be *non-informative*. The parameters are estimated by maximizing the *marginal log likelihood*.

By default  $\alpha_1 = \alpha_2 = \lambda_1 = \lambda_2 = 10^{-6}$ .

Bayesian Ridge Regression is used for regression:

```
>>> from sklearn import linear_model
>>> X = [[0., 0.], [1., 1.], [2., 2.], [3., 3.]]
>>> Y = [0., 1., 2., 3.]
>>> reg = linear_model.BayesianRidge()
>>> reg.fit(X, Y)
BayesianRidge(alpha_1=1e-06, alpha_2=1e-06, compute_score=False, copy_X=True,
    fit_intercept=True, lambda_1=1e-06, lambda_2=1e-06, n_iter=300,
    normalize=False, tol=0.001, verbose=False)
```

After being fitted, the model can then be used to predict new values:

```
>>> reg.predict ([[1, 0]])
array([ 0.50000013])
```

The weights  $w$  of the model can be accessed:

```
>>> reg.coef_
array([ 0.49999993,  0.49999993])
```

Due to the Bayesian framework, the weights found are slightly different to the ones found by [Ordinary Least Squares](#). However, Bayesian Ridge Regression is more robust to ill-posed problem.

### Examples:

- [Bayesian Ridge Regression](#)

## References

- More details can be found in the article [Bayesian Interpolation](#) by MacKay, David J. C.

## Automatic Relevance Determination - ARD

`ARDRegression` is very similar to `Bayesian Ridge Regression`, but can lead to sparser weights  $w^{12}$ . `ARDRegression` poses a different prior over  $w$ , by dropping the assumption of the Gaussian being spherical.

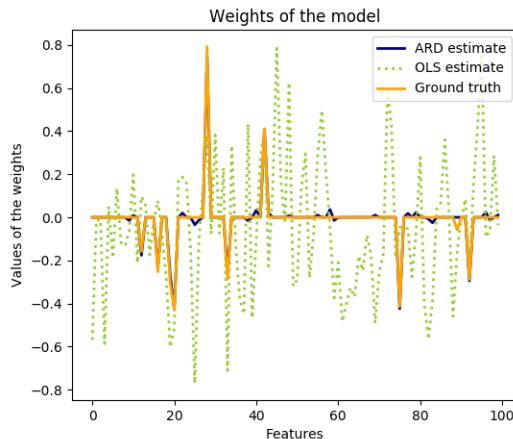

Instead, the distribution over  $w$  is assumed to be an axis-parallel, elliptical Gaussian distribution.

This means each weight  $w_i$  is drawn from a Gaussian distribution, centered on zero and with a precision  $\lambda_i$ :

$$p(w|\lambda) = \mathcal{N}(w|0, A^{-1})$$

with  $\text{diag}(A) = \lambda = \{\lambda_1, \dots, \lambda_p\}$ .

In contrast to `Bayesian Ridge Regression`, each coordinate of  $w_i$  has its own standard deviation  $\lambda_i$ . The prior over all  $\lambda_i$  is chosen to be the same gamma distribution given by hyperparameters  $\lambda_1$  and  $\lambda_2$ .

ARD is also known in the literature as *Sparse Bayesian Learning* and *Relevance Vector Machine*<sup>34</sup>.

## Examples:

- [Automatic Relevance Determination Regression \(ARD\)](#)

<sup>4</sup> Tristan Fletcher: [Relevance Vector Machines explained](#)

## Logistic regression

Logistic regression, despite its name, is a linear model for classification rather than regression. Logistic regression is also known in the literature as logit regression, maximum-entropy classification (MaxEnt) or the log-linear classifier. In this model, the probabilities describing the possible outcomes of a single trial are modeled using a [logistic function](#).

The implementation of logistic regression in scikit-learn can be accessed from class [`LogisticRegression`](#). This implementation can fit binary, One-vs-Rest, or multinomial logistic regression with optional L2 or L1 regularization.

As an optimization problem, binary class L2 penalized logistic regression minimizes the following cost function:

$$\min_{w,c} \frac{1}{2} w^T w + C \sum_{i=1}^n \log(\exp(-y_i(X_i^T w + c)) + 1).$$

Similarly, L1 regularized logistic regression solves the following optimization problem

$$\min_{w,c} \|w\|_1 + C \sum_{i=1}^n \log(\exp(-y_i(X_i^T w + c)) + 1).$$

The solvers implemented in the class [`LogisticRegression`](#) are “liblinear”, “newton-cg”, “lbfgs”, “sag” and “saga”:

The solver “liblinear” uses a coordinate descent (CD) algorithm, and relies on the excellent C++ [LIBLINEAR library](#), which is shipped with scikit-learn. However, the CD algorithm implemented in liblinear cannot learn a true multinomial (multiclass) model; instead, the optimization problem is decomposed in a “one-vs-rest” fashion so separate binary classifiers are trained for all classes. This happens under the hood, so [`LogisticRegression`](#) instances using this solver behave as multiclass classifiers. For L1 penalization [`sklearn.svm.l1\_min\_c`](#) allows to calculate the lower bound for C in order to get a non “null” (all feature weights to zero) model.

The “lbfgs”, “sag” and “newton-cg” solvers only support L2 penalization and are found to converge faster for some high dimensional data. Setting `multi_class` to “multinomial” with these solvers learns a true multinomial logistic regression model<sup>5</sup>, which means that its probability estimates should be better calibrated than the default “one-vs-rest” setting.

The “sag” solver uses a Stochastic Average Gradient descent<sup>6</sup>. It is faster than other solvers for large datasets, when both the number of samples and the number of features are large.

The “saga” solver<sup>7</sup> is a variant of “sag” that also supports the non-smooth `penalty="l1"` option. This is therefore the solver of choice for sparse multinomial logistic regression.

In a nutshell, one may choose the solver with the following rules:

Case	Solver
L1 penalty	“liblinear” or “saga”
Multinomial loss	“lbfgs”, “sag”, “saga” or “newton-cg”
Very Large dataset ( <code>n_samples</code> )	“sag” or “saga”

The “saga” solver is often the best choice. The “liblinear” solver is used by default for historical reasons.

For large dataset, you may also consider using [`SGDClassifier`](#) with ‘log’ loss.

### Examples:

- [L1 Penalty and Sparsity in Logistic Regression](#)

<sup>5</sup> Christopher M. Bishop: Pattern Recognition and Machine Learning, Chapter 4.3.4

<sup>6</sup> Mark Schmidt, Nicolas Le Roux, and Francis Bach: Minimizing Finite Sums with the Stochastic Average Gradient.

<sup>7</sup> Aaron Defazio, Francis Bach, Simon Lacoste-Julien: [SAGA: A Fast Incremental Gradient Method With Support for Non-Strongly Convex Composite Objectives](#).

- *Path with L1- Logistic Regression*
- *Plot multinomial and One-vs-Rest Logistic Regression*
- *Multiclass sparse logistic regression on newsgroups20*
- *MNIST classification using multinomial logistic + L1*

### Differences from liblinear:

There might be a difference in the scores obtained between `LogisticRegression` with `solver=liblinear` or `LinearSVC` and the external liblinear library directly, when `fit_intercept=False` and the `fit_coef_` (or) the data to be predicted are zeroes. This is because for the sample(s) with `decision_function zero`, `LogisticRegression` and `LinearSVC` predict the negative class, while liblinear predicts the positive class. Note that a model with `fit_intercept=False` and having many samples with `decision_function zero`, is likely to be a underfit, bad model and you are advised to set `fit_intercept=True` and increase the `intercept_scaling`.

### Note: Feature selection with sparse logistic regression

A logistic regression with L1 penalty yields sparse models, and can thus be used to perform feature selection, as detailed in [L1-based feature selection](#).

`LogisticRegressionCV` implements Logistic Regression with builtin cross-validation to find out the optimal C parameter. “newton-cg”, “sag”, “saga” and “lbfgs” solvers are found to be faster for high-dimensional dense data, due to warm-starting. For the multiclass case, if `multi_class` option is set to “ovr”, an optimal C is obtained for each class and if the `multi_class` option is set to “multinomial”, an optimal C is obtained by minimizing the cross-entropy loss.

### References:

## Stochastic Gradient Descent - SGD

Stochastic gradient descent is a simple yet very efficient approach to fit linear models. It is particularly useful when the number of samples (and the number of features) is very large. The `partial_fit` method allows only/out-of-core learning.

The classes `SGDClassifier` and `SGDRegressor` provide functionality to fit linear models for classification and regression using different (convex) loss functions and different penalties. E.g., with `loss="log"`, `SGDClassifier` fits a logistic regression model, while with `loss="hinge"` it fits a linear support vector machine (SVM).

### References

- *Stochastic Gradient Descent*

## Perceptron

The `Perceptron` is another simple algorithm suitable for large scale learning. By default:

- It does not require a learning rate.
- It is not regularized (penalized).
- It updates its model only on mistakes.

The last characteristic implies that the Perceptron is slightly faster to train than SGD with the hinge loss and that the resulting models are sparser.

## Passive Aggressive Algorithms

The passive-aggressive algorithms are a family of algorithms for large-scale learning. They are similar to the Perceptron in that they do not require a learning rate. However, contrary to the Perceptron, they include a regularization parameter  $C$ .

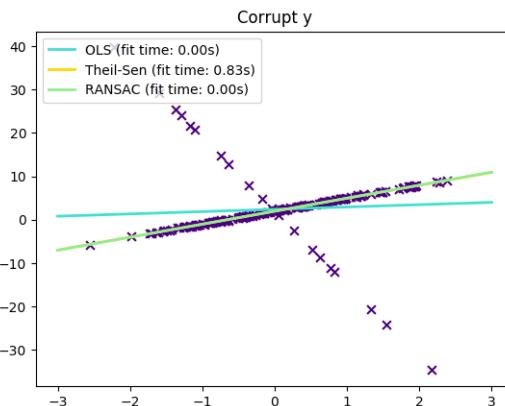

For classification, `PassiveAggressiveClassifier` can be used with `loss='hinge'` (PA-I) or `loss='squared_hinge'` (PA-II). For regression, `PassiveAggressiveRegressor` can be used with `loss='epsilon_insensitive'` (PA-I) or `loss='squared_epsilon_insensitive'` (PA-II).

### References:

## Robustness regression: outliers and modeling errors

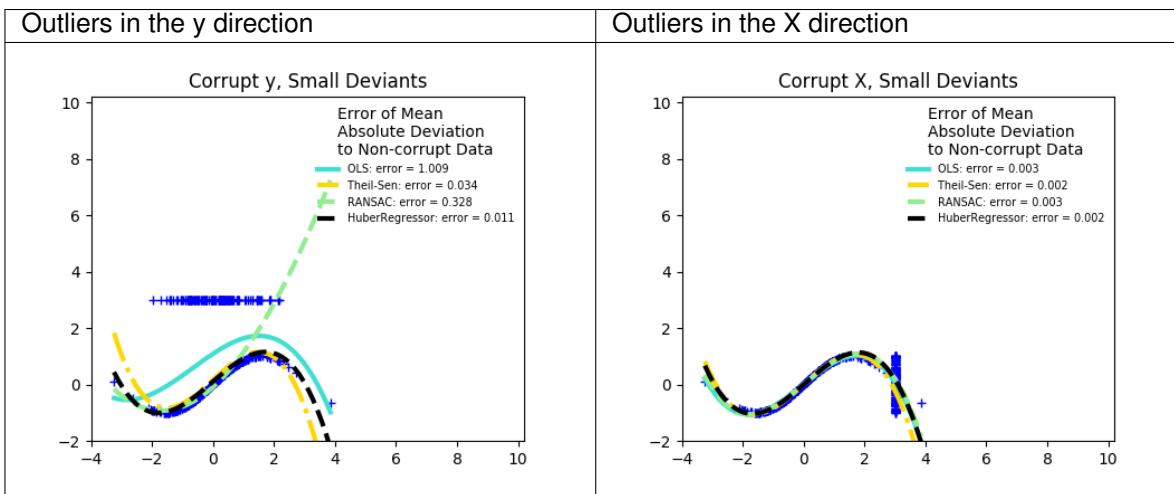

Robust regression is interested in fitting a regression model in the presence of corrupt data: either outliers, or error in the model.

## Different scenario and useful concepts

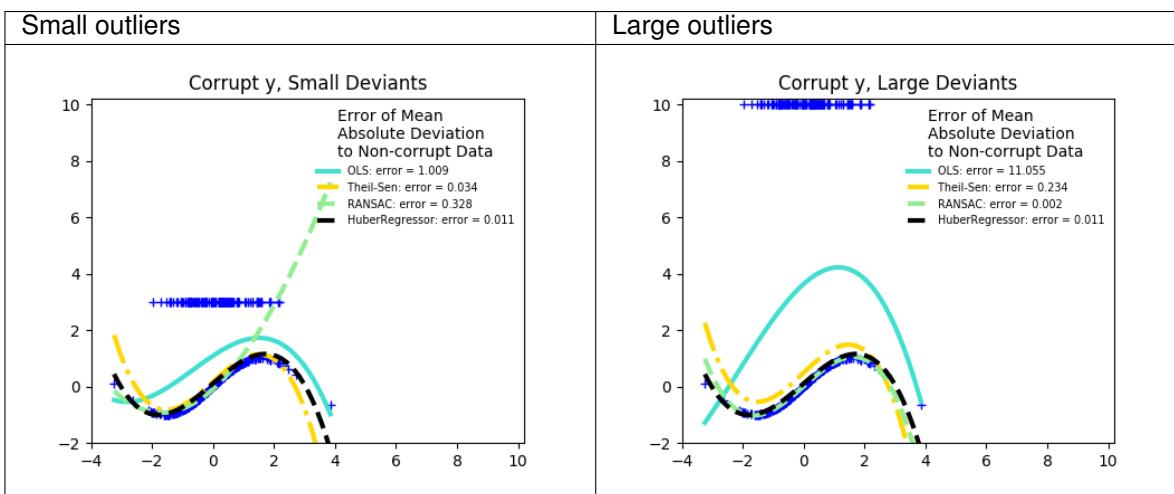

There are different things to keep in mind when dealing with data corrupted by outliers:

- Outliers in X or in y?

- **Fraction of outliers versus amplitude of error**

The number of outlying points matters, but also how much they are outliers.

An important notion of robust fitting is that of breakdown point: the fraction of data that can be outlying for the fit to start missing the inlying data.

Note that in general, robust fitting in high-dimensional setting (large *n\_features*) is very hard. The robust models here will probably not work in these settings.

### Trade-offs: which estimator?

Scikit-learn provides 3 robust regression estimators: [RANSAC](#), [Theil Sen](#) and [HuberRegressor](#)

- [HuberRegressor](#) should be faster than [RANSAC](#) and [Theil Sen](#) unless the number of samples are very large, i.e  $n\_samples \gg n\_features$ . This is because [RANSAC](#) and [Theil Sen](#) fit on smaller subsets of the data. However, both [Theil Sen](#) and [RANSAC](#) are unlikely to be as robust as [HuberRegressor](#) for the default parameters.
- [RANSAC](#) is faster than [Theil Sen](#) and scales much better with the number of samples
- [RANSAC](#) will deal better with large outliers in the y direction (most common situation)
- [Theil Sen](#) will cope better with medium-size outliers in the X direction, but this property will disappear in large dimensional settings.

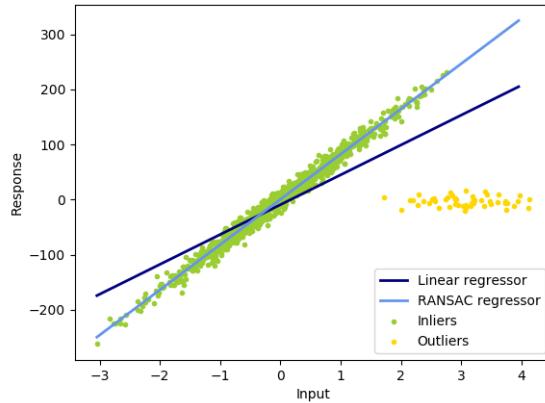

When in doubt, use [RANSAC](#)

## RANSAC: RANdom SAmple Consensus

RANSAC (RANdom SAmple Consensus) fits a model from random subsets of inliers from the complete data set.

RANSAC is a non-deterministic algorithm producing only a reasonable result with a certain probability, which is dependent on the number of iterations (see `max_trials` parameter). It is typically used for linear and non-linear regression problems and is especially popular in the fields of photogrammetric computer vision.

The algorithm splits the complete input sample data into a set of inliers, which may be subject to noise, and outliers, which are e.g. caused by erroneous measurements or invalid hypotheses about the data. The resulting model is then estimated only from the determined inliers.

## Details of the algorithm

Each iteration performs the following steps:

1. Select `min_samples` random samples from the original data and check whether the set of data is valid (see `is_data_valid`).
2. Fit a model to the random subset (`base_estimator.fit`) and check whether the estimated model is valid (see `is_model_valid`).
3. Classify all data as inliers or outliers by calculating the residuals to the estimated model (`base_estimator.predict(X) - y`) - all data samples with absolute residuals smaller than the `residual_threshold` are considered as inliers.
4. Save fitted model as best model if number of inlier samples is maximal. In case the current estimated model has the same number of inliers, it is only considered as the best model if it has better score.

These steps are performed either a maximum number of times (`max_trials`) or until one of the special stop criteria are met (see `stop_n_inliers` and `stop_score`). The final model is estimated using all inlier samples (consensus set) of the previously determined best model.

The `is_data_valid` and `is_model_valid` functions allow to identify and reject degenerate combinations of random sub-samples. If the estimated model is not needed for identifying degenerate cases, `is_data_valid` should be used as it is called prior to fitting the model and thus leading to better computational performance.

**Examples:**

- Robust linear model estimation using RANSAC
- Robust linear estimator fitting

**References:**

**Theil-Sen estimator: generalized-median-based estimator**

The `TheilSenRegressor` estimator uses a generalization of the median in multiple dimensions. It is thus robust to multivariate outliers. Note however that the robustness of the estimator decreases quickly with the dimensionality of the problem. It loses its robustness properties and becomes no better than an ordinary least squares in high dimension.

**Examples:**

- Theil-Sen Regression
- Robust linear estimator fitting

**References:**

- [https://en.wikipedia.org/wiki/Theil%20%93Sen\\_estimator](https://en.wikipedia.org/wiki/Theil%20%93Sen_estimator)

**Theoretical considerations**

`TheilSenRegressor` is comparable to the *Ordinary Least Squares (OLS)* in terms of asymptotic efficiency and as an unbiased estimator. In contrast to OLS, Theil-Sen is a non-parametric method which means it makes no assumption about the underlying distribution of the data. Since Theil-Sen is a median-based estimator, it is more robust against corrupted data aka outliers. In univariate setting, Theil-Sen has a breakdown point of about 29.3% in case of a simple linear regression which means that it can tolerate arbitrary corrupted data of up to 29.3%.

The implementation of `TheilSenRegressor` in scikit-learn follows a generalization to a multivariate linear regression model [\[#f1\]](#) using the spatial median which is a generalization of the median to multiple dimensions<sup>9</sup>.

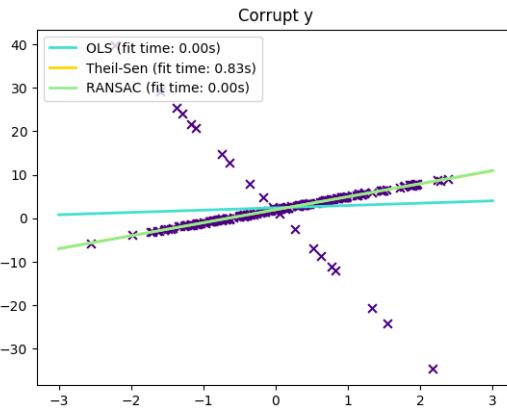

In terms of time and space complexity, Theil-Sen scales according to

$$\binom{n_{samples}}{n_{subsamples}}$$

---

<sup>9</sup>

20. Kärkkäinen and S. Äyrämö: On Computation of Spatial Median for Robust Data Mining.

which makes it infeasible to be applied exhaustively to problems with a large number of samples and features. Therefore, the magnitude of a subpopulation can be chosen to limit the time and space complexity by considering only a random subset of all possible combinations.

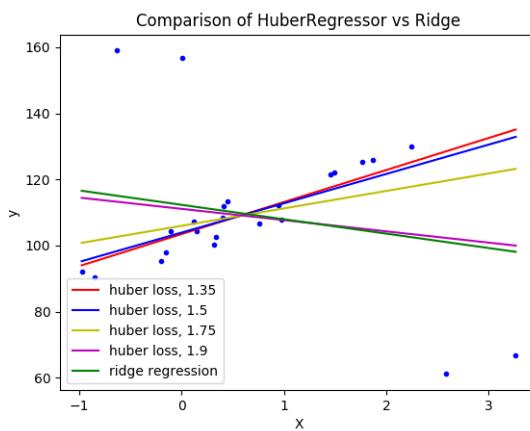

#### Examples:

- *Theil-Sen Regression*

## Huber Regression

The `HuberRegressor` is different to `Ridge` because it applies a linear loss to samples that are classified as outliers. A sample is classified as an inlier if the absolute error of that sample is lesser than a certain threshold. It differs from `TheilSenRegressor` and `RANSACRegressor` because it does not ignore the effect of the outliers but gives a lesser weight to them.

The loss function that `HuberRegressor` minimizes is given by

$$\min_{w,\sigma} \sum_{i=1}^n \left( \sigma + H_m \left( \frac{X_i w - y_i}{\sigma} \right) \sigma \right) + \alpha \|w\|_2^2$$

where

$$H_m(z) = \begin{cases} z^2, & \text{if } |z| < \epsilon, \\ 2\epsilon|z| - \epsilon^2, & \text{otherwise} \end{cases}$$

It is advised to set the parameter `epsilon` to 1.35 to achieve 95% statistical efficiency.

## Notes

The `HuberRegressor` differs from using `SGDRegressor` with loss set to `huber` in the following ways.

- `HuberRegressor` is scaling invariant. Once `epsilon` is set, scaling X and y down or up by different values would produce the same robustness to outliers as before. as compared to `SGDRegressor` where `epsilon` has to be set again when X and y are scaled.
- `HuberRegressor` should be more efficient to use on data with small number of samples while `SGDRegressor` needs a number of passes on the training data to produce the same robustness.

### Examples:

- `HuberRegressor vs Ridge on dataset with strong outliers`

### References:

Also, this estimator is different from the R implementation of Robust Regression (<http://www.ats.ucla.edu/stat/r/dae/rreg.htm>) because the R implementation does a weighted least squares implementation with weights given to each sample on the basis of how much the residual is greater than a certain threshold.

## Polynomial regression: extending linear models with basis functions

One common pattern within machine learning is to use linear models trained on nonlinear functions of the data. This approach maintains the generally fast performance of linear methods, while allowing them to fit a much wider range of data.

For example, a simple linear regression can be extended by constructing **polynomial features** from the coefficients. In the standard linear regression case, you might have a model that looks like this for two-dimensional data:

$$\hat{y}(w, x) = w_0 + w_1 x_1 + w_2 x_2$$

If we want to fit a paraboloid to the data instead of a plane, we can combine the features in second-order polynomials, so that the model looks like this:

$$\hat{y}(w, x) = w_0 + w_1 x_1 + w_2 x_2 + w_3 x_1 x_2 + w_4 x_1^2 + w_5 x_2^2$$

The (sometimes surprising) observation is that this is *still a linear model*: to see this, imagine creating a new variable

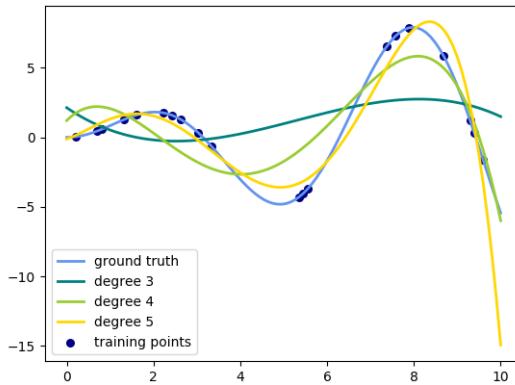

$$z = [x_1, x_2, x_1 x_2, x_1^2, x_2^2]$$

With this re-labeling of the data, our problem can be written

$$\hat{y}(w, x) = w_0 + w_1 z_1 + w_2 z_2 + w_3 z_3 + w_4 z_4 + w_5 z_5$$

We see that the resulting *polynomial regression* is in the same class of linear models we'd considered above (i.e. the model is linear in  $w$ ) and can be solved by the same techniques. By considering linear fits within a higher-dimensional space built with these basis functions, the model has the flexibility to fit a much broader range of data.

Here is an example of applying this idea to one-dimensional data, using polynomial features of varying degrees:

This figure is created using the `PolynomialFeatures` preprocessor. This preprocessor transforms an input data matrix into a new data matrix of a given degree. It can be used as follows:

```
>>> from sklearn.preprocessing import PolynomialFeatures
>>> import numpy as np
>>> X = np.arange(6).reshape(3, 2)
>>> X
array([[0, 1],
       [2, 3],
       [4, 5]])
>>> poly = PolynomialFeatures(degree=2)
>>> poly.fit_transform(X)
array([[ 1.,  0.,  1.,  0.,  0.,  1.],
       [ 1.,  2.,  3.,  4.,  6.,  9.],
       [ 1.,  4.,  5., 16., 20., 25.]])
```

The features of  $X$  have been transformed from  $[x_1, x_2]$  to  $[1, x_1, x_2, x_1^2, x_1x_2, x_2^2]$ , and can now be used within any linear model.

This sort of preprocessing can be streamlined with the `Pipeline` tools. A single object representing a simple polynomial regression can be created and used as follows:

```
>>> from sklearn.preprocessing import PolynomialFeatures
>>> from sklearn.linear_model import LinearRegression
>>> from sklearn.pipeline import Pipeline
>>> import numpy as np
>>> model = Pipeline([('poly', PolynomialFeatures(degree=3)),
...                   ('linear', LinearRegression(fit_intercept=False))])
>>> # fit to an order-3 polynomial data
>>> x = np.arange(5)
>>> y = 3 - 2 * x + x ** 2 - x ** 3
```

```
>>> model = model.fit(x[:, np.newaxis], y)
>>> model.named_steps['linear'].coef_
array([ 3., -2.,  1., -1.])
```

The linear model trained on polynomial features is able to exactly recover the input polynomial coefficients.

In some cases it's not necessary to include higher powers of any single feature, but only the so-called *interaction features* that multiply together at most  $d$  distinct features. These can be gotten from `PolynomialFeatures` with the setting `interaction_only=True`.

For example, when dealing with boolean features,  $x_i^n = x_i$  for all  $n$  and is therefore useless; but  $x_i x_j$  represents the conjunction of two booleans. This way, we can solve the XOR problem with a linear classifier:

```
>>> from sklearn.linear_model import Perceptron
>>> from sklearn.preprocessing import PolynomialFeatures
>>> import numpy as np
>>> X = np.array([[0, 0], [0, 1], [1, 0], [1, 1]])
>>> y = X[:, 0] ^ X[:, 1]
>>> y
array([0, 1, 1, 0])
>>> X = PolynomialFeatures(interaction_only=True).fit_transform(X).astype(int)
>>> X
array([[1, 0, 0, 0],
       [1, 0, 1, 0],
       [1, 1, 0, 0],
       [1, 1, 1, 1]])
>>> clf = Perceptron(fit_intercept=False, n_iter=10, shuffle=False).fit(X, y)
```

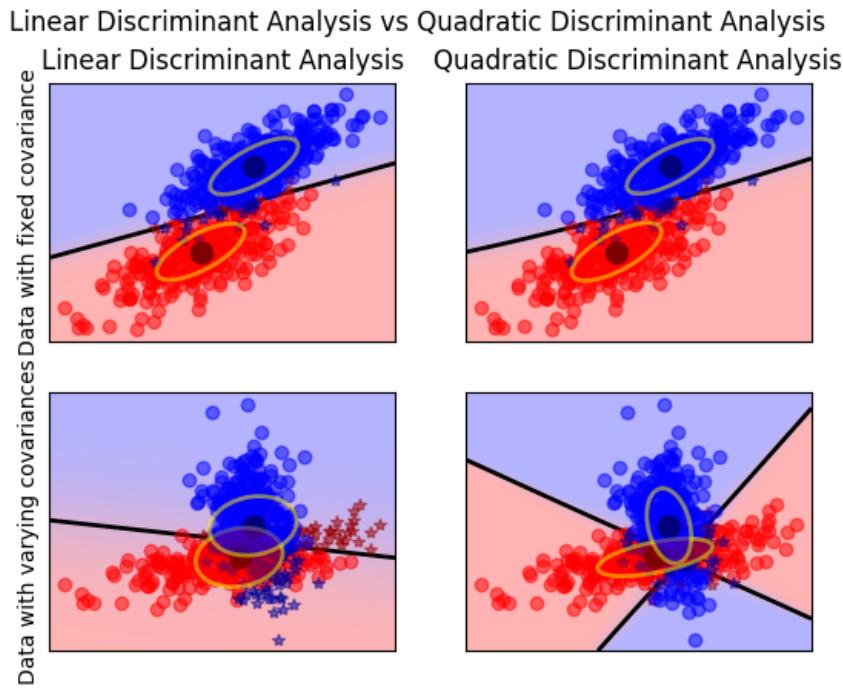

And the classifier “predictions” are perfect:

```
>>> clf.predict(X)
array([0, 1, 1, 0])
>>> clf.score(X, y)
1.0
```

### 3.1.2 Linear and Quadratic Discriminant Analysis

Linear Discriminant Analysis (`discriminant_analysis.LinearDiscriminantAnalysis`) and Quadratic Discriminant Analysis (`discriminant_analysis.QuadraticDiscriminantAnalysis`) are two classic classifiers, with, as their names suggest, a linear and a quadratic decision surface, respectively.

These classifiers are attractive because they have closed-form solutions that can be easily computed, are inherently multiclass, have proven to work well in practice and have no hyperparameters to tune.

The plot shows decision boundaries for Linear Discriminant Analysis and Quadratic Discriminant Analysis. The bottom row demonstrates that Linear Discriminant Analysis can only learn linear boundaries, while Quadratic Discriminant Analysis can learn quadratic boundaries and is therefore more flexible.

**Examples:**

*Linear and Quadratic Discriminant Analysis with covariance ellipsoid:* Comparison of LDA and QDA on synthetic data.

## Dimensionality reduction using Linear Discriminant Analysis

*discriminant\_analysis.LinearDiscriminantAnalysis* can be used to perform supervised dimensionality reduction, by projecting the input data to a linear subspace consisting of the directions which maximize the separation between classes (in a precise sense discussed in the mathematics section below). The dimension of the output is necessarily less than the number of classes, so this is a in general a rather strong dimensionality reduction, and only makes sense in a multiclass setting.

This is implemented in *discriminant\_analysis.LinearDiscriminantAnalysis.transform*. The desired dimensionality can be set using the `n_components` constructor parameter. This parameter has no influence on *discriminant\_analysis.LinearDiscriminantAnalysis.fit* or *discriminant\_analysis.LinearDiscriminantAnalysis.predict*.

**Examples:**

*Comparison of LDA and PCA 2D projection of Iris dataset:* Comparison of LDA and PCA for dimensionality reduction of the Iris dataset

## Mathematical formulation of the LDA and QDA classifiers

Both LDA and QDA can be derived from simple probabilistic models which model the class conditional distribution of the data  $P(X|y = k)$  for each class  $k$ . Predictions can then be obtained by using Bayes' rule:

$$P(y = k|X) = \frac{P(X|y = k)P(y = k)}{P(X)} = \frac{P(X|y = k)P(y = k)}{\sum_l P(X|y = l) \cdot P(y = l)}$$

and we select the class  $k$  which maximizes this conditional probability.

More specifically, for linear and quadratic discriminant analysis,  $P(X|y)$  is modelled as a multivariate Gaussian distribution with density:

$$p(X|y = k) = \frac{1}{(2\pi)^n |\Sigma_k|^{1/2}} \exp\left(-\frac{1}{2}(X - \mu_k)^t \Sigma_k^{-1} (X - \mu_k)\right)$$

To use this model as a classifier, we just need to estimate from the training data the class priors  $P(y = k)$  (by the proportion of instances of class  $k$ ), the class means  $\mu_k$  (by the empirical sample class means) and the covariance matrices (either by the empirical sample class covariance matrices, or by a regularized estimator: see the section on shrinkage below).

In the case of LDA, the Gaussians for each class are assumed to share the same covariance matrix:  $\Sigma_k = \Sigma$  for all  $k$ . This leads to linear decision surfaces between, as can be seen by comparing the log-probability ratios  $\log[P(y = k|X)/P(y = l|X)]$ :

$$\log\left(\frac{P(y = k|X)}{P(y = l|X)}\right) = 0 \Leftrightarrow (\mu_k - \mu_l)\Sigma^{-1}X = \frac{1}{2}(\mu_k^t \Sigma^{-1} \mu_k - \mu_l^t \Sigma^{-1} \mu_l)$$

In the case of QDA, there are no assumptions on the covariance matrices  $\Sigma_k$  of the Gaussians, leading to quadratic decision surfaces. See<sup>3</sup> for more details.

---

### Note: Relation with Gaussian Naive Bayes

If in the QDA model one assumes that the covariance matrices are diagonal, then the inputs are assumed to be conditionally independent in each class, and the resulting classifier is equivalent to the Gaussian Naive Bayes classifier `naive_bayes.GaussianNB`.

---

## Mathematical formulation of LDA dimensionality reduction

To understand the use of LDA in dimensionality reduction, it is useful to start with a geometric reformulation of the LDA classification rule explained above. We write  $K$  for the total number of target classes. Since in LDA we assume that all classes have the same estimated covariance  $\Sigma$ , we can rescale the data so that this covariance is the identity:

$$X^* = D^{-1/2}U^t X \text{ with } \Sigma = UDU^t$$

Then one can show that to classify a data point after scaling is equivalent to finding the estimated class mean  $\mu_k^*$  which is closest to the data point in the Euclidean distance. But this can be done just as well after projecting on the  $K - 1$  affine subspace  $H_K$  generated by all the  $\mu_k^*$  for all classes. This shows that, implicit in the LDA classifier, there is a dimensionality reduction by linear projection onto a  $K - 1$  dimensional space.

We can reduce the dimension even more, to a chosen  $L$ , by projecting onto the linear subspace  $H_L$  which maximize the variance of the  $\mu_k^*$  after projection (in effect, we are doing a form of PCA for the transformed class means  $\mu_k^*$ ). This  $L$  corresponds to the `n_components` parameter used in the `discriminant_analysis.LinearDiscriminantAnalysis.transform` method. See<sup>3</sup> for more details.

---

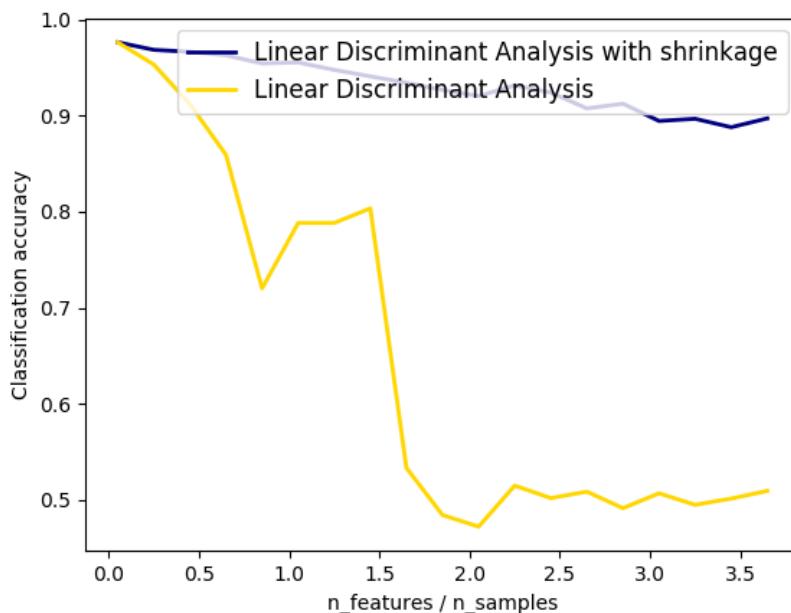

<sup>3</sup> "The Elements of Statistical Learning", Hastie T., Tibshirani R., Friedman J., Section 4.3, p.106-119, 2008.

## Shrinkage

Shrinkage is a tool to improve estimation of covariance matrices in situations where the number of training samples is small compared to the number of features. In this scenario, the empirical sample covariance is a poor estimator. Shrinkage LDA can be used by setting the shrinkage parameter of the [discriminant\\_analysis](#). [LinearDiscriminantAnalysis](#) class to ‘auto’. This automatically determines the optimal shrinkage parameter in an analytic way following the lemma introduced by Ledoit and Wolf<sup>4</sup>. Note that currently shrinkage only works when setting the solver parameter to ‘lsqr’ or ‘eigen’.

The shrinkage parameter can also be manually set between 0 and 1. In particular, a value of 0 corresponds to no shrinkage (which means the empirical covariance matrix will be used) and a value of 1 corresponds to complete shrinkage (which means that the diagonal matrix of variances will be used as an estimate for the covariance matrix). Setting this parameter to a value between these two extrema will estimate a shrunk version of the covariance matrix.

crimiant Analysis vs. shrinkage Linear Discriminant Analysis (1 discriminativ

## Estimation algorithms

The default solver is ‘svd’. It can perform both classification and transform, and it does not rely on the calculation of the covariance matrix. This can be an advantage in situations where the number of features is large. However, the ‘svd’ solver cannot be used with shrinkage.

The ‘lsqr’ solver is an efficient algorithm that only works for classification. It supports shrinkage.

The ‘eigen’ solver is based on the optimization of the between class scatter to within class scatter ratio. It can be used for both classification and transform, and it supports shrinkage. However, the ‘eigen’ solver needs to compute the covariance matrix, so it might not be suitable for situations with a high number of features.

### 3.1.3 Kernel ridge regression

Kernel ridge regression (KRR) [M2012] combines *Ridge Regression* (linear least squares with l2-norm regularization) with the kernel trick. It thus learns a linear function in the space induced by the respective kernel and the data. For non-linear kernels, this corresponds to a non-linear function in the original space.

The form of the model learned by *KernelRidge* is identical to support vector regression (SVR). However, different loss functions are used: KRR uses squared error loss while support vector regression uses  $\epsilon$ -insensitive loss, both combined with l2 regularization. In contrast to SVR, fitting *KernelRidge* can be done in closed-form and is typically faster for medium-sized datasets. On the other hand, the learned model is non-sparse and thus slower than SVR, which learns a sparse model for  $\epsilon > 0$ , at prediction-time.

The following figure compares *KernelRidge* and SVR on an artificial dataset, which consists of a sinusoidal target function and strong noise added to every fifth datapoint. The learned model of *KernelRidge* and SVR is plotted, where both complexity/regularization and bandwidth of the RBF kernel have been optimized using grid-search. The learned functions are very similar; however, fitting *KernelRidge* is approx. seven times faster than fitting SVR (both with grid-search). However, prediction of 100000 target values is more than three times faster with SVR since it has learned a sparse model using only approx. 1/3 of the 100 training datapoints as support vectors.

The next figure compares the time for fitting and prediction of *KernelRidge* and SVR for different sizes of the training set. Fitting *KernelRidge* is faster than SVR for medium-sized training sets (less than 1000 samples); however, for larger training sets SVR scales better. With regard to prediction time, SVR is faster than *KernelRidge* for all sizes of the training set because of the learned sparse solution. Note that the degree of sparsity and thus the prediction time depends on the parameters  $\epsilon$  and  $C$  of the SVR;  $\epsilon = 0$  would correspond to a dense model.

## References:

### 3.1.4 Support Vector Machines

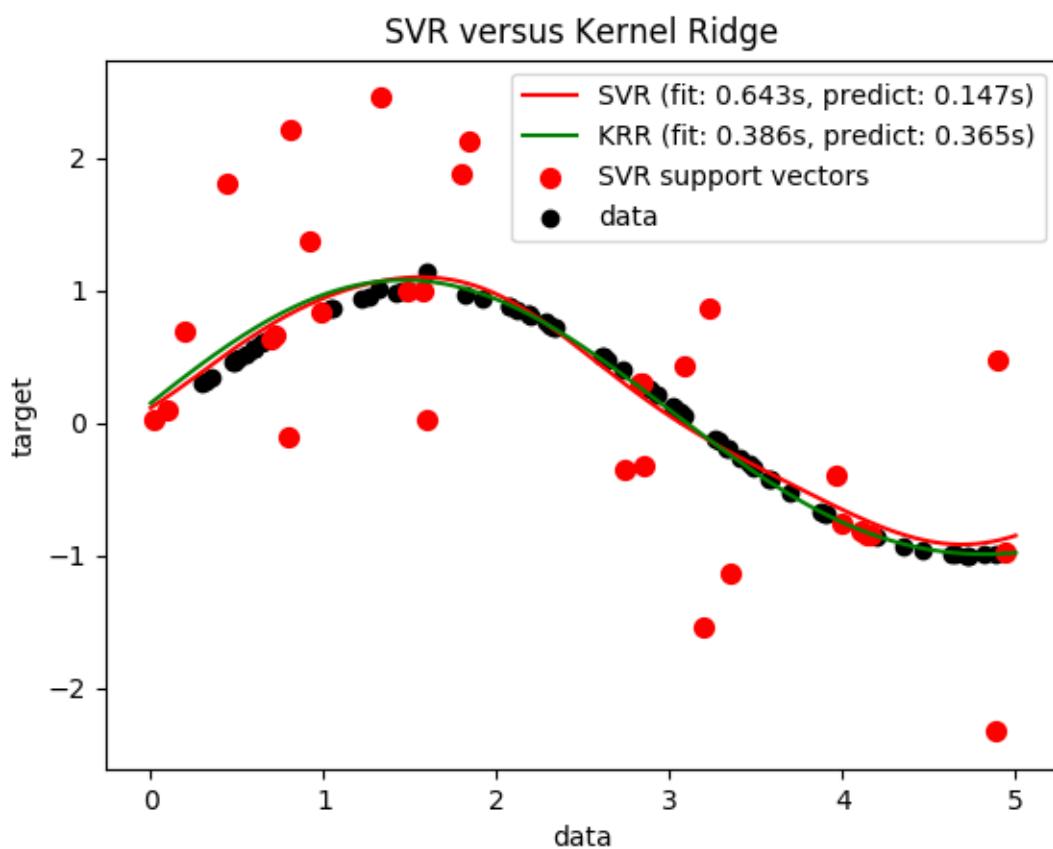

**Support vector machines (SVMs)** are a set of supervised learning methods used for *classification*, *regression* and *outliers detection*.

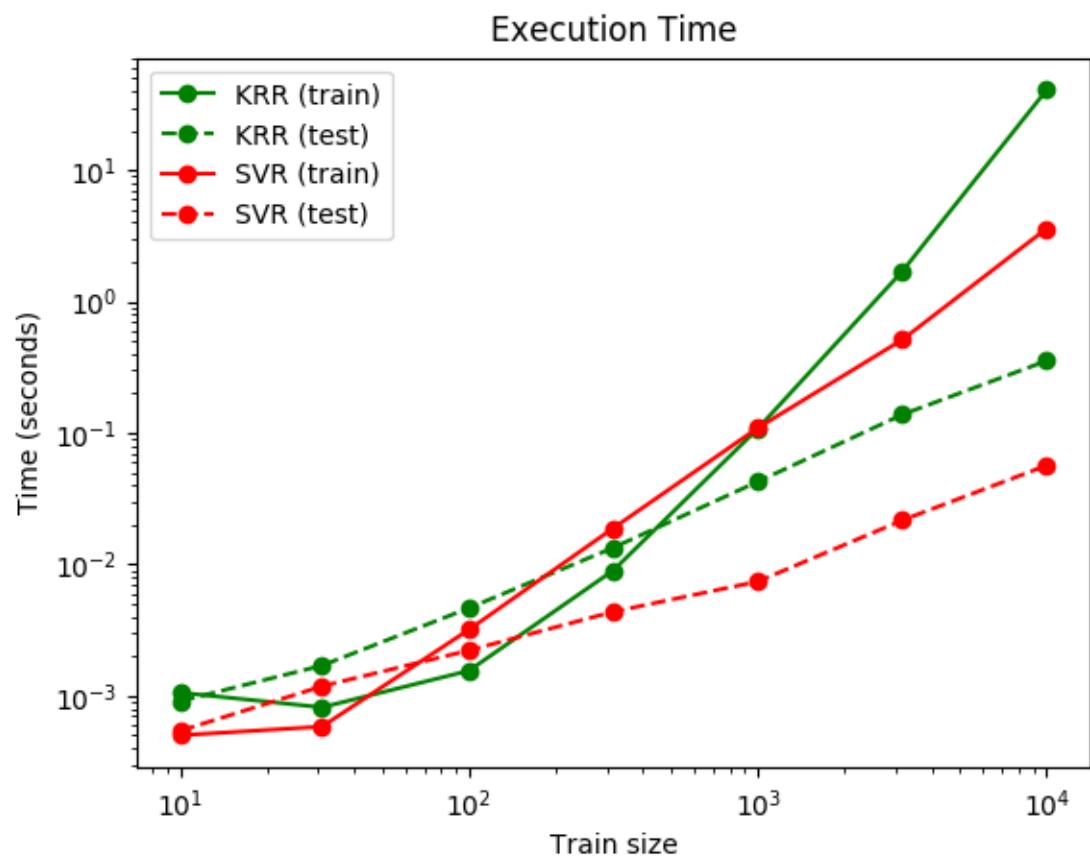

The advantages of support vector machines are:

- Effective in high dimensional spaces.
- Still effective in cases where number of dimensions is greater than the number of samples.
- Uses a subset of training points in the decision function (called support vectors), so it is also memory efficient.
- Versatile: different *Kernel functions* can be specified for the decision function. Common kernels are provided, but it is also possible to specify custom kernels.

The disadvantages of support vector machines include:

- If the number of features is much greater than the number of samples, avoid over-fitting in choosing *Kernel functions* and regularization term is crucial.

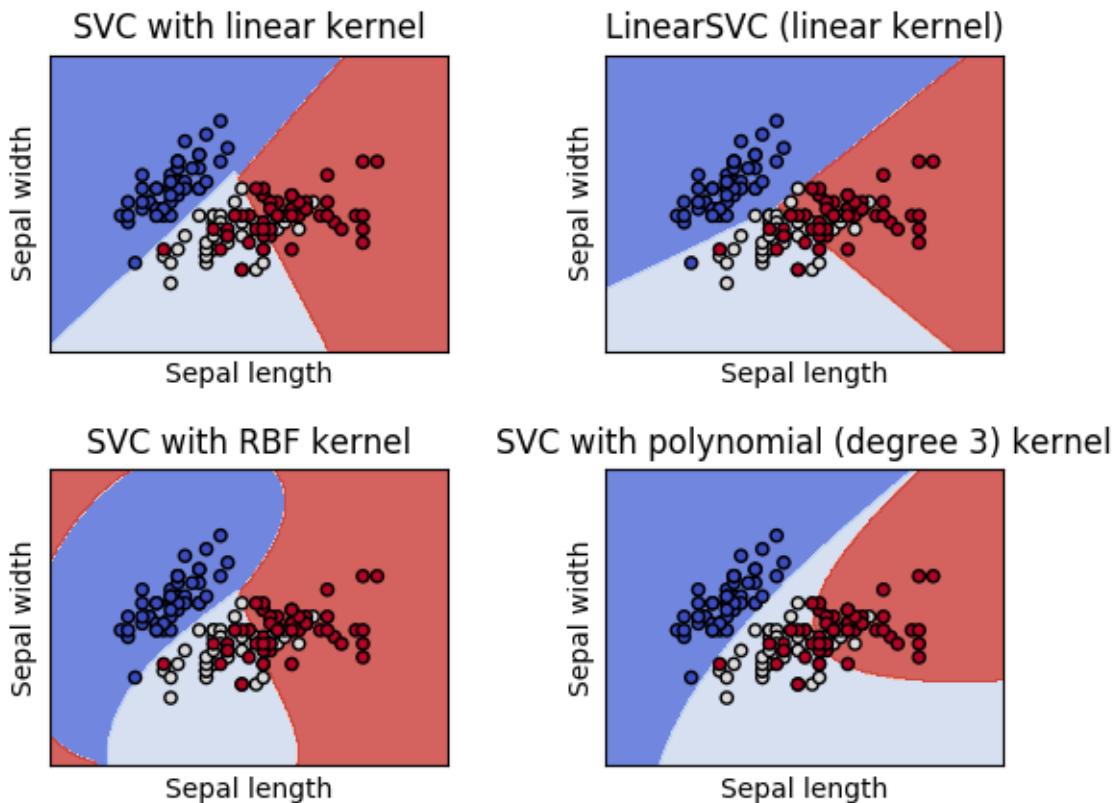

- SVMs do not directly provide probability estimates, these are calculated using an expensive five-fold cross-validation (see [Scores and probabilities](#), below).

The support vector machines in scikit-learn support both dense (`numpy.ndarray` and convertible to that by `numpy.asarray`) and sparse (any `scipy.sparse`) sample vectors as input. However, to use an SVM to make predictions for sparse data, it must have been fit on such data. For optimal performance, use C-ordered `numpy.ndarray` (dense) or `scipy.sparse.csr_matrix` (sparse) with `dtype=float64`.

## Classification

`SVC`, `NuSVC` and `LinearSVC` are classes capable of performing multi-class classification on a dataset.

`SVC` and `NuSVC` are similar methods, but accept slightly different sets of parameters and have different mathematical formulations (see section [Mathematical formulation](#)). On the other hand, `LinearSVC` is another implementation of Support Vector Classification for the case of a linear kernel. Note that `LinearSVC` does not accept keyword `kernel`, as this is assumed to be linear. It also lacks some of the members of `SVC` and `NuSVC`, like `support_`.

As other classifiers, `SVC`, `NuSVC` and `LinearSVC` take as input two arrays: an array `X` of size [`n_samples`, `n_features`] holding the training samples, and an array `y` of class labels (strings or integers), size [`n_samples`]:

```
>>> from sklearn import svm
>>> X = [[0, 0], [1, 1]]
>>> y = [0, 1]
>>> clf = svm.SVC()
```

```
>>> clf.fit(X, y)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)
```

After being fitted, the model can then be used to predict new values:

```
>>> clf.predict([[2., 2.]])
array([1])
```

SVMs decision function depends on some subset of the training data, called the support vectors. Some properties of these support vectors can be found in members `support_vectors_`, `support_` and `n_support`:

```
>>> # get support vectors
>>> clf.support_vectors_
array([[ 0.,  0.],
       [ 1.,  1.]])
>>> # get indices of support vectors
>>> clf.support_
array([0, 1]...)
>>> # get number of support vectors for each class
>>> clf.n_support_
array([1, 1]...)
```

## Multi-class classification

`SVC` and `NuSVC` implement the “one-against-one” approach (Knerr et al., 1990) for multi-class classification. If `n_class` is the number of classes, then `n_class * (n_class - 1) / 2` classifiers are constructed and each one trains data from two classes. To provide a consistent interface with other classifiers, the `decision_function_shape` option allows to aggregate the results of the “one-against-one” classifiers to a decision function of shape (`n_samples`, `n_classes`):

```
>>> X = [[0, 1], [2, 3]
>>> Y = [0, 1, 2, 3]
>>> clf = svm.SVC(decision_function_shape='ovo')
>>> clf.fit(X, Y)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovo', degree=3, gamma='auto', kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)
>>> dec = clf.decision_function([[1]])
>>> dec.shape[1] # 4 classes: 4*3/2 = 6
6
>>> clf.decision_function_shape = "ovr"
>>> dec = clf.decision_function([[1]])
>>> dec.shape[1] # 4 classes
4
```

On the other hand, `LinearSVC` implements “one-vs-the-rest” multi-class strategy, thus training `n_class` models. If there are only two classes, only one model is trained:

```
>>> lin_clf = svm.LinearSVC()
>>> lin_clf.fit(X, Y)
LinearSVC(C=1.0, class_weight=None, dual=True, fit_intercept=True,
```

```

intercept_scaling=1, loss='squared_hinge', max_iter=1000,
multi_class='ovr', penalty='l2', random_state=None, tol=0.0001,
verbose=0)
>>> dec = lin_clf.decision_function([[1]])
>>> dec.shape[1]
4

```

See [Mathematical formulation](#) for a complete description of the decision function.

Note that the [`LinearSVC`](#) also implements an alternative multi-class strategy, the so-called multi-class SVM formulated by Crammer and Singer, by using the option `multi_class='crammer_singer'`. This method is consistent, which is not true for one-vs-rest classification. In practice, one-vs-rest classification is usually preferred, since the results are mostly similar, but the runtime is significantly less.

For “one-vs-rest” [`LinearSVC`](#) the attributes `coef_` and `intercept_` have the shape `[n_class, n_features]` and `[n_class]` respectively. Each row of the coefficients corresponds to one of the `n_class` many “one-vs-rest” classifiers and similar for the intercepts, in the order of the “one” class.

In the case of “one-vs-one” [`SVC`](#), the layout of the attributes is a little more involved. In the case of having a linear kernel, The layout of `coef_` and `intercept_` is similar to the one described for [`LinearSVC`](#) described above, except that the shape of `coef_` is `[n_class * (n_class - 1) / 2, n_features]`, corresponding to as many binary classifiers. The order for classes 0 to n is “0 vs 1”, “0 vs 2”, ... “0 vs n”, “1 vs 2”, “1 vs 3”, “1 vs n”, ... “n-1 vs n”.

The shape of `dual_coef_` is `[n_class-1, n_SV]` with a somewhat hard to grasp layout. The columns correspond to the support vectors involved in any of the `n_class * (n_class - 1) / 2` “one-vs-one” classifiers. Each of the support vectors is used in `n_class - 1` classifiers. The `n_class - 1` entries in each row correspond to the dual coefficients for these classifiers.

This might be made more clear by an example:

Consider a three class problem with class 0 having three support vectors  $v_0^0, v_0^1, v_0^2$  and class 1 and 2 having two support vectors  $v_1^0, v_1^1$  and  $v_2^0, v_2^1$  respectively. For each support vector  $v_i^j$ , there are two dual coefficients. Let's call the coefficient of support vector  $v_i^j$  in the classifier between classes  $i$  and  $k$   $\alpha_{i,k}^j$ . Then `dual_coef_` looks like this:

$\alpha_{0,1}^0$	$\alpha_{0,2}^0$	Coefficients for SVs of class 0
$\alpha_{0,1}^1$	$\alpha_{0,2}^1$	
$\alpha_{0,1}^2$	$\alpha_{0,2}^2$	
$\alpha_{1,0}^0$	$\alpha_{1,2}^0$	Coefficients for SVs of class 1
$\alpha_{1,0}^1$	$\alpha_{1,2}^1$	
$\alpha_{2,0}^0$	$\alpha_{2,1}^0$	Coefficients for SVs of class 2
$\alpha_{2,0}^1$	$\alpha_{2,1}^1$	

## Scores and probabilities

The [`SVC`](#) method `decision_function` gives per-class scores for each sample (or a single score per sample in the binary case). When the constructor option `probability` is set to `True`, class membership probability estimates (from the methods `predict_proba` and `predict_log_proba`) are enabled. In the binary case, the probabilities are calibrated using Platt scaling: logistic regression on the SVM’s scores, fit by an additional cross-validation on the training data. In the multiclass case, this is extended as per Wu et al. (2004).

Needless to say, the cross-validation involved in Platt scaling is an expensive operation for large datasets. In addition, the probability estimates may be inconsistent with the scores, in the sense that the “argmax” of the scores may not be the argmax of the probabilities. (E.g., in binary classification, a sample may be labeled by `predict` as belonging to a class that has probability  $<\frac{1}{2}$  according to `predict_proba`.) Platt’s method is also known to have theoret-

ical issues. If confidence scores are required, but these do not have to be probabilities, then it is advisable to set `probability=False` and use `decision_function` instead of `predict_proba`.

## Unbalanced problems

In problems where it is desired to give more importance to certain classes or certain individual samples keywords `class_weight` and `sample_weight` can be used.

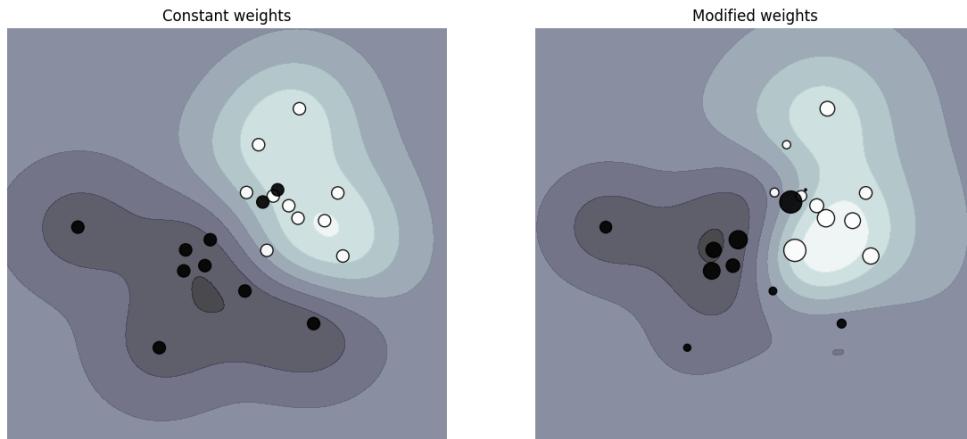

`SVC` (but not `NuSVC`) implement a keyword `class_weight` in the `fit` method. It's a dictionary of the form `{class_label : value}`, where `value` is a floating point number  $> 0$  that sets the parameter `C` of class `class_label` to  $C * \text{value}$ .

`SVC`, `NuSVC`, `SVR`, `NuSVR` and `OneClassSVM` implement also weights for individual samples in method `fit` through keyword `sample_weight`. Similar to `class_weight`, these set the parameter `C` for the  $i$ -th example to  $C * \text{sample\_weight}[i]$ .

## Examples:

- *Plot different SVM classifiers in the iris dataset,*
- *SVM: Maximum margin separating hyperplane,*

- *SVM: Separating hyperplane for unbalanced classes*
- *SVM-Anova: SVM with univariate feature selection,*
- *Non-linear SVM*
- *SVM: Weighted samples,*

## Regression

The method of Support Vector Classification can be extended to solve regression problems. This method is called Support Vector Regression.

The model produced by support vector classification (as described above) depends only on a subset of the training data, because the cost function for building the model does not care about training points that lie beyond the margin. Analogously, the model produced by Support Vector Regression depends only on a subset of the training data, because the cost function for building the model ignores any training data close to the model prediction.

There are three different implementations of Support Vector Regression: `SVR`, `NuSVR` and `LinearSVR`. `LinearSVR` provides a faster implementation than `SVR` but only considers linear kernels, while `NuSVR` implements a slightly different formulation than `SVR` and `LinearSVR`. See [Implementation details](#) for further details.

As with classification classes, the fit method will take as argument vectors `X`, `y`, only that in this case `y` is expected to have floating point values instead of integer values:

```
>>> from sklearn import svm
>>> X = [[0, 0], [2, 2]]
>>> y = [0.5, 2.5]
>>> clf = svm.SVR()
>>> clf.fit(X, y)
SVR(C=1.0, cache_size=200, coef0=0.0, degree=3, epsilon=0.1, gamma='auto',
     kernel='rbf', max_iter=-1, shrinking=True, tol=0.001, verbose=False)
>>> clf.predict([[1, 1]])
array([ 1.5])
```

**Examples:**

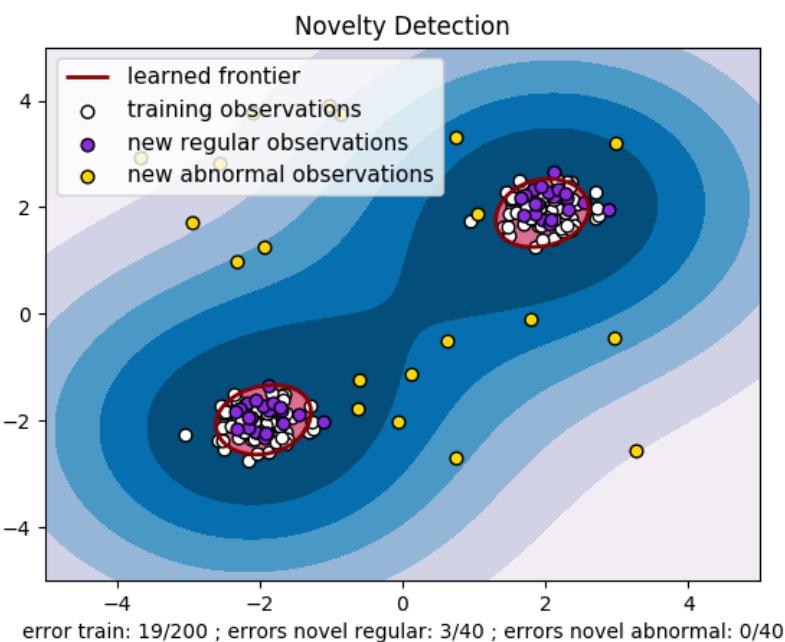

- *Support Vector Regression (SVR) using linear and non-linear kernels*

**Density estimation, novelty detection**

One-class SVM is used for novelty detection, that is, given a set of samples, it will detect the soft boundary of that set so as to classify new points as belonging to that set or not. The class that implements this is called `OneClassSVM`.

In this case, as it is a type of unsupervised learning, the fit method will only take as input an array X, as there are no class labels.

See, section [Novelty and Outlier Detection](#) for more details on this usage.

**Examples:**

- *One-class SVM with non-linear kernel (RBF)*
- *Species distribution modeling*

**Complexity**

Support Vector Machines are powerful tools, but their compute and storage requirements increase rapidly with the number of training vectors. The core of an SVM is a quadratic programming problem (QP), separating support vectors from the rest of the training data. The QP solver used by this `libsvm`-based implementation scales between  $O(n_{\text{features}} \times n_{\text{samples}}^2)$  and  $O(n_{\text{features}} \times n_{\text{samples}}^3)$  depending on how efficiently the `libsvm` cache is used in practice (dataset dependent). If the data is very sparse  $n_{\text{features}}$  should be replaced by the average number of non-zero features in a sample vector.

Also note that for the linear case, the algorithm used in `LinearSVC` by the liblinear implementation is much more efficient than its `libsvm`-based `SVC` counterpart and can scale almost linearly to millions of samples and/or features.

## Tips on Practical Use

- **Avoiding data copy:** For `SVC`, `SVR`, `NuSVC` and `NuSVR`, if the data passed to certain methods is not C-ordered contiguous, and double precision, it will be copied before calling the underlying C implementation. You can check whether a given numpy array is C-contiguous by inspecting its `flags` attribute.

For `LinearSVC` (and `LogisticRegression`) any input passed as a numpy array will be copied and converted to the liblinear internal sparse data representation (double precision floats and int32 indices of non-zero components). If you want to fit a large-scale linear classifier without copying a dense numpy C-contiguous double precision array as input we suggest to use the `SGDClassifier` class instead. The objective function can be configured to be almost the same as the `LinearSVC` model.

- **Kernel cache size:** For `SVC`, `SVR`, `nusvc` and `NuSVR`, the size of the kernel cache has a strong impact on run times for larger problems. If you have enough RAM available, it is recommended to set `cache_size` to a higher value than the default of 200(MB), such as 500(MB) or 1000(MB).
- **Setting C:** `C` is 1 by default and it's a reasonable default choice. If you have a lot of noisy observations you should decrease it. It corresponds to regularize more the estimation.
- Support Vector Machine algorithms are not scale invariant, so **it is highly recommended to scale your data**. For example, scale each attribute on the input vector `X` to [0,1] or [-1,+1], or standardize it to have mean 0 and variance 1. Note that the *same* scaling must be applied to the test vector to obtain meaningful results. See section `Preprocessing data` for more details on scaling and normalization.
- Parameter `nu` in `NuSVC/OneClassSVM/NuSVR` approximates the fraction of training errors and support vectors.
- In `SVC`, if data for classification are unbalanced (e.g. many positive and few negative), set `class_weight='balanced'` and/or try different penalty parameters `C`.
- The underlying `LinearSVC` implementation uses a random number generator to select features when fitting the model. It is thus not uncommon, to have slightly different results for the same input data. If that happens, try with a smaller `tol` parameter.
- Using L1 penalization as provided by `LinearSVC(loss='l2', penalty='l1', dual=False)` yields a sparse solution, i.e. only a subset of feature weights is different from zero and contribute to the decision function. Increasing `C` yields a more complex model (more feature are selected). The `C` value that yields a “null” model (all weights equal to zero) can be calculated using `l1_min_c`.

## Kernel functions

The *kernel function* can be any of the following:

- linear:  $\langle x, x' \rangle$ .
- polynomial:  $(\gamma \langle x, x' \rangle + r)^d$ .  $d$  is specified by keyword `degree`,  $r$  by `coef0`.
- rbf:  $\exp(-\gamma \|x - x'\|^2)$ .  $\gamma$  is specified by keyword `gamma`, must be greater than 0.
- sigmoid ( $\tanh(\gamma \langle x, x' \rangle + r)$ ), where  $r$  is specified by `coef0`.

Different kernels are specified by keyword `kernel` at initialization:

```
>>> linear_svc = svm.SVC(kernel='linear')
>>> linear_svc.kernel
'linear'
```

```
>>> rbf_svc = svm.SVC(kernel='rbf')
>>> rbf_svc.kernel
'rbf'
```

## Custom Kernels

You can define your own kernels by either giving the kernel as a python function or by precomputing the Gram matrix. Classifiers with custom kernels behave the same way as any other classifiers, except that:

- Field `support_vectors_` is now empty, only indices of support vectors are stored in `support_`
- A reference (and not a copy) of the first argument in the `fit()` method is stored for future reference. If that array changes between the use of `fit()` and `predict()` you will have unexpected results.

## Using Python functions as kernels

You can also use your own defined kernels by passing a function to the keyword `kernel` in the constructor.

Your kernel must take as arguments two matrices of shape `(n_samples_1, n_features)`, `(n_samples_2, n_features)` and return a kernel matrix of shape `(n_samples_1, n_samples_2)`.

The following code defines a linear kernel and creates a classifier instance that will use that kernel:

```
>>> import numpy as np
>>> from sklearn import svm
>>> def my_kernel(X, Y):
...     return np.dot(X, Y.T)
...
>>> clf = svm.SVC(kernel=my_kernel)
```

### Examples:

- *SVM with custom kernel.*

## Using the Gram matrix

Set `kernel='precomputed'` and pass the Gram matrix instead of X in the fit method. At the moment, the kernel values between *all* training vectors and the test vectors must be provided.

```
>>> import numpy as np
>>> from sklearn import svm
>>> X = np.array([[0, 0], [1, 1]])
>>> y = [0, 1]
>>> clf = svm.SVC(kernel='precomputed')
>>> # linear kernel computation
>>> gram = np.dot(X, X.T)
>>> clf.fit(gram, y)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto',
    kernel='precomputed', max_iter=-1, probability=False,
    random_state=None, shrinking=True, tol=0.001, verbose=False)
>>> # predict on training examples
```

```
>>> clf.predict(gram)
array([0, 1])
```

## Parameters of the RBF Kernel

When training an SVM with the *Radial Basis Function* (RBF) kernel, two parameters must be considered:  $C$  and  $\gamma$ . The parameter  $C$ , common to all SVM kernels, trades off misclassification of training examples against simplicity of the decision surface. A low  $C$  makes the decision surface smooth, while a high  $C$  aims at classifying all training examples correctly.  $\gamma$  defines how much influence a single training example has. The larger  $\gamma$  is, the closer other examples must be to be affected.

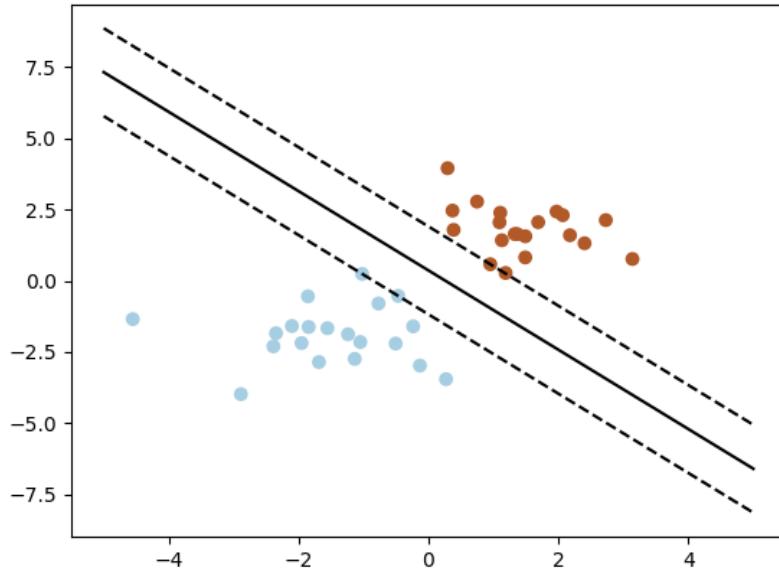

Proper choice of  $C$  and  $\gamma$  is critical to the SVM's performance. One is advised to use `sklearn.model_selection.GridSearchCV` with  $C$  and  $\gamma$  spaced exponentially far apart to choose good values.

### Examples:

- *RBF SVM parameters*

## Mathematical formulation

A support vector machine constructs a hyper-plane or set of hyper-planes in a high or infinite dimensional space, which can be used for classification, regression or other tasks. Intuitively, a good separation is achieved by the hyper-plane that has the largest distance to the nearest training data points of any class (so-called functional margin), since in general the larger the margin the lower the generalization error of the classifier.

## SVC

Given training vectors  $x_i \in \mathbb{R}^p$ ,  $i=1, \dots, n$ , in two classes, and a vector  $y \in \{1, -1\}^n$ , SVC solves the following primal problem:

$$\begin{aligned} & \min_{w,b,\zeta} \frac{1}{2} w^T w + C \sum_{i=1}^n \zeta_i \\ & \text{subject to } y_i(w^T \phi(x_i) + b) \geq 1 - \zeta_i, \\ & \zeta_i \geq 0, i = 1, \dots, n \end{aligned}$$

Its dual is

$$\begin{aligned} & \min_{\alpha} \frac{1}{2} \alpha^T Q \alpha - e^T \alpha \\ & \text{subject to } y^T \alpha = 0 \\ & 0 \leq \alpha_i \leq C, i = 1, \dots, n \end{aligned}$$

where  $e$  is the vector of all ones,  $C > 0$  is the upper bound,  $Q$  is an  $n$  by  $n$  positive semidefinite matrix,  $Q_{ij} \equiv y_i y_j K(x_i, x_j)$ , where  $K(x_i, x_j) = \phi(x_i)^T \phi(x_j)$  is the kernel. Here training vectors are implicitly mapped into a higher (maybe infinite) dimensional space by the function  $\phi$ .

The decision function is:

$$\text{sgn}\left(\sum_{i=1}^n y_i \alpha_i K(x_i, x) + \rho\right)$$

---

**Note:** While SVM models derived from `libsvm` and `liblinear` use `C` as regularization parameter, most other estimators use `alpha`. The exact equivalence between the amount of regularization of two models depends on the exact objective function optimized by the model. For example, when the estimator used is `sklearn.linear_model.Ridge` regression, the relation between them is given as  $C = \frac{1}{alpha}$ .

---

This parameters can be accessed through the members `dual_coef_` which holds the product  $y_i \alpha_i$ , `support_vectors_` which holds the support vectors, and `intercept_` which holds the independent term  $\rho$ :

- “Support-vector networks”, C. Cortes, V. Vapnik - Machine Learning, 20, 273-297 (1995).

## NuSVC

We introduce a new parameter  $\nu$  which controls the number of support vectors and training errors. The parameter  $\nu \in (0, 1]$  is an upper bound on the fraction of training errors and a lower bound of the fraction of support vectors.

It can be shown that the  $\nu$ -SVC formulation is a reparametrization of the  $C$ -SVC and therefore mathematically equivalent.

## SVR

Given training vectors  $x_i \in \mathbb{R}^p$ ,  $i=1, \dots, n$ , and a vector  $y \in \mathbb{R}^n$   $\varepsilon$ -SVR solves the following primal problem:

$$\begin{aligned} & \min_{w, b, \zeta, \zeta^*} \frac{1}{2} w^T w + C \sum_{i=1}^n (\zeta_i + \zeta_i^*) \\ & \text{subject to } y_i - w^T \phi(x_i) - b \leq \varepsilon + \zeta_i, \\ & \quad w^T \phi(x_i) + b - y_i \leq \varepsilon + \zeta_i^*, \\ & \quad \zeta_i, \zeta_i^* \geq 0, i = 1, \dots, n \end{aligned}$$

Its dual is

$$\begin{aligned} & \min_{\alpha, \alpha^*} \frac{1}{2} (\alpha - \alpha^*)^T Q (\alpha - \alpha^*) + \varepsilon e^T (\alpha + \alpha^*) - y^T (\alpha - \alpha^*) \\ & \text{subject to } e^T (\alpha - \alpha^*) = 0 \\ & \quad 0 \leq \alpha_i, \alpha_i^* \leq C, i = 1, \dots, n \end{aligned}$$

where  $e$  is the vector of all ones,  $C > 0$  is the upper bound,  $Q$  is an  $n$  by  $n$  positive semidefinite matrix,  $Q_{ij} \equiv K(x_i, x_j) = \phi(x_i)^T \phi(x_j)$  is the kernel. Here training vectors are implicitly mapped into a higher (maybe infinite) dimensional space by the function  $\phi$ .

The decision function is:

$$\sum_{i=1}^n (\alpha_i - \alpha_i^*) K(x_i, x) + \rho$$

These parameters can be accessed through the members `dual_coef_` which holds the difference  $\alpha_i - \alpha_i^*$ , `support_vectors_` which holds the support vectors, and `intercept_` which holds the independent term  $\rho$

### 3.1.5 Stochastic Gradient Descent

**Stochastic Gradient Descent (SGD)** is a simple yet very efficient approach to discriminative learning of linear classifiers under convex loss functions such as (linear) [Support Vector Machines](#) and [Logistic Regression](#). Even though

SGD has been around in the machine learning community for a long time, it has received a considerable amount of attention just recently in the context of large-scale learning.

SGD has been successfully applied to large-scale and sparse machine learning problems often encountered in text classification and natural language processing. Given that the data is sparse, the classifiers in this module easily scale to problems with more than  $10^5$  training examples and more than  $10^5$  features.

The advantages of Stochastic Gradient Descent are:

- Efficiency.
- Ease of implementation (lots of opportunities for code tuning).

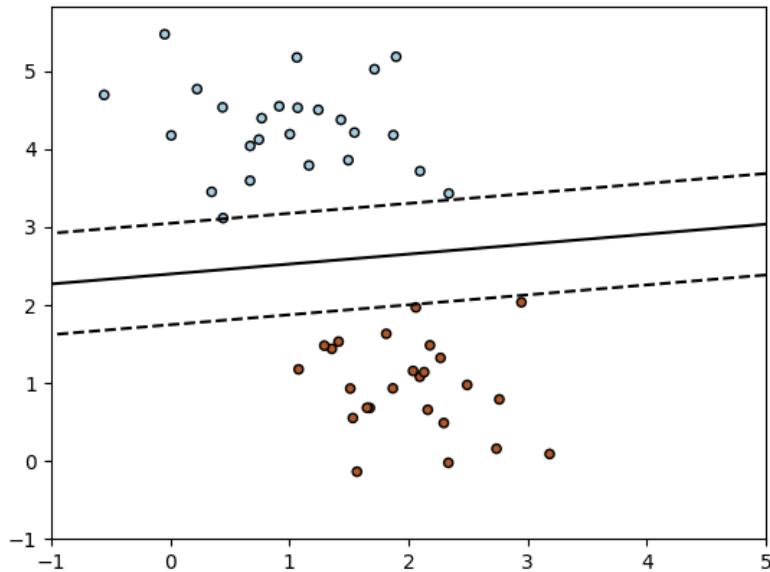

The disadvantages of Stochastic Gradient Descent include:

- SGD requires a number of hyperparameters such as the regularization parameter and the number of iterations.
- SGD is sensitive to feature scaling.

## Classification

**Warning:** Make sure you permute (shuffle) your training data before fitting the model or use `shuffle=True` to shuffle after each iteration.

The class `SGDClassifier` implements a plain stochastic gradient descent learning routine which supports different loss functions and penalties for classification.

As other classifiers, SGD has to be fitted with two arrays: an array X of size [n\_samples, n\_features] holding the training samples, and an array Y of size [n\_samples] holding the target values (class labels) for the training samples:

```
>>> from sklearn.linear_model import SGDClassifier
>>> X = [[0., 0.], [1., 1.]]
```

```
>>> y = [0, 1]
>>> clf = SGDClassifier(loss="hinge", penalty="l2")
>>> clf.fit(X, y)
SGDClassifier(alpha=0.0001, average=False, class_weight=None, epsilon=0.1,
              eta0=0.0, fit_intercept=True, l1_ratio=0.15,
              learning_rate='optimal', loss='hinge', n_iter=5, n_jobs=1,
              penalty='l2', power_t=0.5, random_state=None, shuffle=True,
              verbose=0, warm_start=False)
```

After being fitted, the model can then be used to predict new values:

```
>>> clf.predict([[2., 2.]])
array([1])
```

SGD fits a linear model to the training data. The member `coef_` holds the model parameters:

```
>>> clf.coef_
array([[ 9.9...,  9.9...]])
```

Member `intercept_` holds the intercept (aka offset or bias):

```
>>> clf.intercept_
array([-9.9...])
```

Whether or not the model should use an intercept, i.e. a biased hyperplane, is controlled by the parameter `fit_intercept`.

To get the signed distance to the hyperplane use `SGDClassifier.decision_function`:

```
>>> clf.decision_function([[2., 2.]])
array([ 29.6...])
```

The concrete loss function can be set via the `loss` parameter. `SGDClassifier` supports the following loss functions:

- `loss="hinge"`: (soft-margin) linear Support Vector Machine,
- `loss="modified_huber"`: smoothed hinge loss,
- `loss="log"`: logistic regression,
- and all regression losses below.

The first two loss functions are lazy, they only update the model parameters if an example violates the margin constraint, which makes training very efficient and may result in sparser models, even when L2 penalty is used.

Using `loss="log"` or `loss="modified_huber"` enables the `predict_proba` method, which gives a vector of probability estimates  $P(y|x)$  per sample  $x$ :

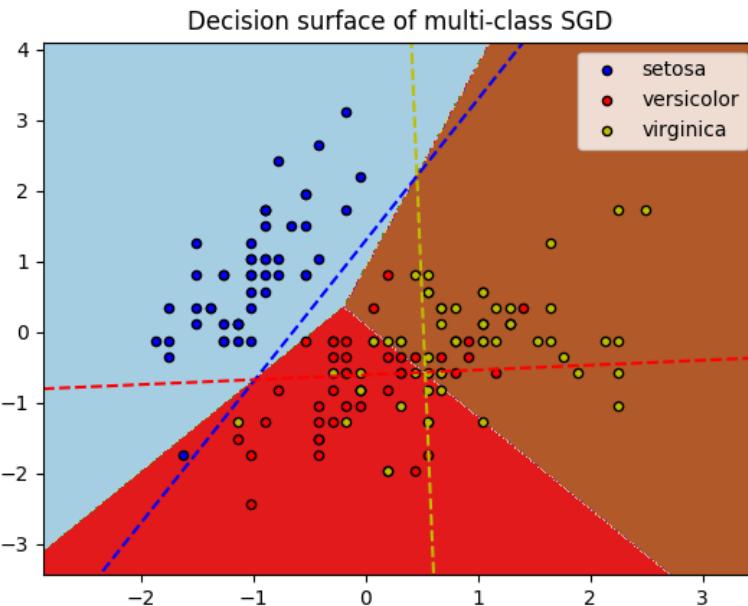

```
>>> clf = SGDClassifier(loss="log").fit(X, y)
>>> clf.predict_proba([[1., 1.]])
array([[ 0.00...,  0.99...]])
```

The concrete penalty can be set via the `penalty` parameter. SGD supports the following penalties:

- `penalty="l2"`: L2 norm penalty on `coef_`.
- `penalty="l1"`: L1 norm penalty on `coef_`.
- `penalty="elasticnet"`: Convex combination of L2 and L1;  $(1 - l1\_ratio) * L2 + l1\_ratio * L1$ .

The default setting is `penalty="l2"`. The L1 penalty leads to sparse solutions, driving most coefficients to zero. The Elastic Net solves some deficiencies of the L1 penalty in the presence of highly correlated attributes. The parameter `l1_ratio` controls the convex combination of L1 and L2 penalty.

`SGDClassifier` supports multi-class classification by combining multiple binary classifiers in a “one versus all” (OVA) scheme. For each of the  $K$  classes, a binary classifier is learned that discriminates between that and all other  $K - 1$  classes. At testing time, we compute the confidence score (i.e. the signed distances to the hyperplane) for each classifier and choose the class with the highest confidence. The Figure below illustrates the OVA approach on the iris dataset. The dashed lines represent the three OVA classifiers; the background colors show the decision surface induced by the three classifiers.

In the case of multi-class classification `coef_` is a two-dimensionally array of shape=[`n_classes`, `n_features`] and `intercept_` is a one dimensional array of shape=[`n_classes`]. The i-th row of `coef_` holds the weight vector of the OVA classifier for the i-th class; classes are indexed in ascending order (see attribute `classes_`). Note that, in principle, since they allow to create a probability model, `loss="log"` and `loss="modified_huber"` are more suitable for one-vs-all classification.

`SGDClassifier` supports both weighted classes and weighted instances via the fit parameters `class_weight` and `sample_weight`. See the examples below and the doc string of `SGDClassifier.fit` for further information.

### Examples:

- [SGD: Maximum margin separating hyperplane](#),
- [Plot multi-class SGD on the iris dataset](#)
- [SGD: Weighted samples](#)
- [Comparing various online solvers](#)
- [SVM: Separating hyperplane for unbalanced classes](#) (See the Note)

`SGDClassifier` supports averaged SGD (ASGD). Averaging can be enabled by setting `average=True`. ASGD works by averaging the coefficients of the plain SGD over each iteration over a sample. When using ASGD the learning rate can be larger and even constant leading on some datasets to a speed up in training time.

For classification with a logistic loss, another variant of SGD with an averaging strategy is available with Stochastic Average Gradient (SAG) algorithm, available as a solver in `LogisticRegression`.

## Regression

The class `SGDRegressor` implements a plain stochastic gradient descent learning routine which supports different loss functions and penalties to fit linear regression models. `SGDRegressor` is well suited for regression problems with a large number of training samples ( $> 10.000$ ), for other problems we recommend `Ridge`, `Lasso`, or `ElasticNet`.

The concrete loss function can be set via the `loss` parameter. `SGDRegressor` supports the following loss functions:

- `loss="squared_loss"`: Ordinary least squares,
- `loss="huber"`: Huber loss for robust regression,
- `loss="epsilon_insensitive"`: linear Support Vector Regression.

The Huber and epsilon-insensitive loss functions can be used for robust regression. The width of the insensitive region has to be specified via the parameter `epsilon`. This parameter depends on the scale of the target variables.

`SGDRegressor` supports averaged SGD as `SGDClassifier`. Averaging can be enabled by setting `average=True`.

For regression with a squared loss and a l2 penalty, another variant of SGD with an averaging strategy is available with Stochastic Average Gradient (SAG) algorithm, available as a solver in `Ridge`.

## Stochastic Gradient Descent for sparse data

---

**Note:** The sparse implementation produces slightly different results than the dense implementation due to a shrunk learning rate for the intercept.

---

There is built-in support for sparse data given in any matrix in a format supported by `scipy.sparse`. For maximum efficiency, however, use the CSR matrix format as defined in `scipy.sparse.csr_matrix`.

### Examples:

- *Classification of text documents using sparse features*

## Complexity

The major advantage of SGD is its efficiency, which is basically linear in the number of training examples. If  $X$  is a matrix of size  $(n, p)$  training has a cost of  $O(knp)$ , where  $k$  is the number of iterations (epochs) and  $\bar{p}$  is the average number of non-zero attributes per sample.

Recent theoretical results, however, show that the runtime to get some desired optimization accuracy does not increase as the training set size increases.

## Tips on Practical Use

- Stochastic Gradient Descent is sensitive to feature scaling, so it is highly recommended to scale your data. For example, scale each attribute on the input vector  $X$  to  $[0,1]$  or  $[-1,+1]$ , or standardize it to have mean 0 and variance 1. Note that the *same* scaling must be applied to the test vector to obtain meaningful results. This can be easily done using StandardScaler:

```
from sklearn.preprocessing import StandardScaler
scaler = StandardScaler()
scaler.fit(X_train) # Don't cheat - fit only on training data
X_train = scaler.transform(X_train)
X_test = scaler.transform(X_test) # apply same transformation to test data
```

If your attributes have an intrinsic scale (e.g. word frequencies or indicator features) scaling is not needed.

- Finding a reasonable regularization term  $\alpha$  is best done using GridSearchCV, usually in the range  $10^{0\star\star-n} \text{np.arange}(1, 7)$ .
- Empirically, we found that SGD converges after observing approx.  $10^6$  training samples. Thus, a reasonable first guess for the number of iterations is  $n_{\text{iter}} = \text{np.ceil}(10^{\star\star 6} / n)$ , where  $n$  is the size of the training set.
- If you apply SGD to features extracted using PCA we found that it is often wise to scale the feature values by some constant  $c$  such that the average L2 norm of the training data equals one.
- We found that Averaged SGD works best with a larger number of features and a higher eta0

## Mathematical formulation

Given a set of training examples  $(x_1, y_1), \dots, (x_n, y_n)$  where  $x_i \in \mathbf{R}^m$  and  $y_i \in \{-1, 1\}$ , our goal is to learn a linear scoring function  $f(x) = w^T x + b$  with model parameters  $w \in \mathbf{R}^m$  and intercept  $b \in \mathbf{R}$ . In order to make predictions, we simply look at the sign of  $f(x)$ . A common choice to find the model parameters is by minimizing the regularized training error given by

$$E(w, b) = \frac{1}{n} \sum_{i=1}^n L(y_i, f(x_i)) + \alpha R(w)$$

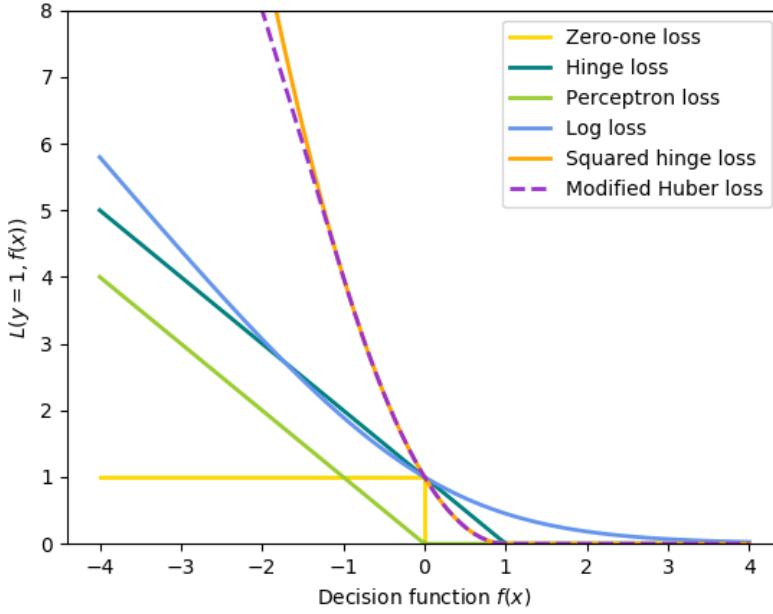

where  $L$  is a loss function that measures model (mis)fit and  $R$  is a regularization term (aka penalty) that penalizes model complexity;  $\alpha > 0$  is a non-negative hyperparameter.

Different choices for  $L$  entail different classifiers such as

- Hinge: (soft-margin) Support Vector Machines.
- Log: Logistic Regression.
- Least-Squares: Ridge Regression.
- Epsilon-Insensitive: (soft-margin) Support Vector Regression.

All of the above loss functions can be regarded as an upper bound on the misclassification error (Zero-one loss) as shown in the Figure below.

Popular choices for the regularization term  $R$  include:

- L2 norm:  $R(w) := \frac{1}{2} \sum_{i=1}^n w_i^2$ ,
- L1 norm:  $R(w) := \sum_{i=1}^n |w_i|$ , which leads to sparse solutions.
- Elastic Net:  $R(w) := \frac{\rho}{2} \sum_{i=1}^n w_i^2 + (1 - \rho) \sum_{i=1}^n |w_i|$ , a convex combination of L2 and L1, where  $\rho$  is given by `l1_ratio`.

The Figure below shows the contours of the different regularization terms in the parameter space when  $R(w) = 1$ .

## SGD

Stochastic gradient descent is an optimization method for unconstrained optimization problems. In contrast to (batch) gradient descent, SGD approximates the true gradient of  $E(w, b)$  by considering a single training example at a time.

The class `SGDClassifier` implements a first-order SGD learning routine. The algorithm iterates over the training examples and for each example updates the model parameters according to the update rule given by

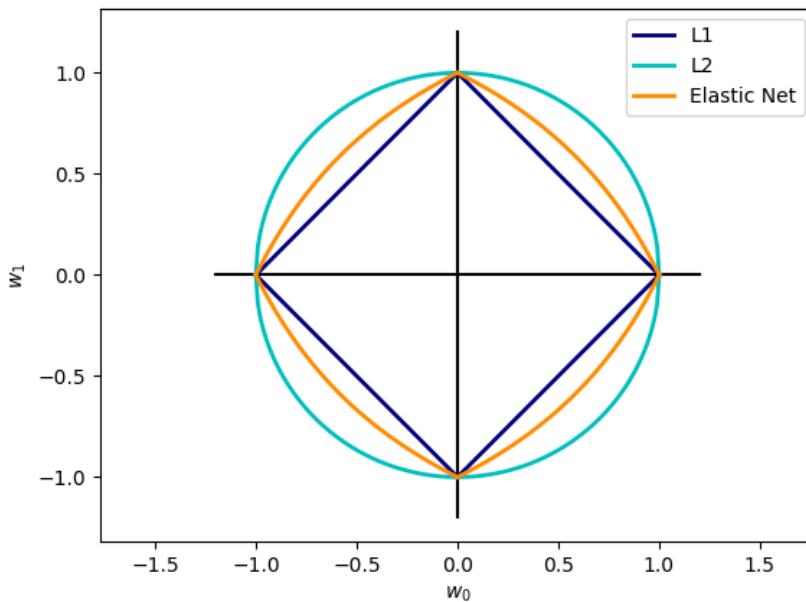

$$w \leftarrow w - \eta \left( \alpha \frac{\partial R(w)}{\partial w} + \frac{\partial L(w^T x_i + b, y_i)}{\partial w} \right)$$

where  $\eta$  is the learning rate which controls the step-size in the parameter space. The intercept  $b$  is updated similarly but without regularization.

The learning rate  $\eta$  can be either constant or gradually decaying. For classification, the default learning rate schedule (`learning_rate='optimal'`) is given by

$$\eta^{(t)} = \frac{1}{\alpha(t_0 + t)}$$

where  $t$  is the time step (there are a total of `n_samples * n_iter` time steps),  $t_0$  is determined based on a heuristic proposed by Léon Bottou such that the expected initial updates are comparable with the expected size of the weights (this assuming that the norm of the training samples is approx. 1). The exact definition can be found in `_init_t` in `BaseSGD`.

For regression the default learning rate schedule is inverse scaling (`learning_rate='invscaling'`), given by

$$\eta^{(t)} = \frac{\text{eta}_0}{t^{\text{power\_t}}}$$

where `eta_0` and `power_t` are hyperparameters chosen by the user via `eta0` and `power_t`, resp.

For a constant learning rate use `learning_rate='constant'` and use `eta0` to specify the learning rate.

The model parameters can be accessed through the members `coef_` and `intercept_`:

- Member `coef_` holds the weights  $w$
- Member `intercept_` holds  $b$

## Implementation details

The implementation of SGD is influenced by the [Stochastic Gradient SVM](#) of Léon Bottou. Similar to `SvmSGD`, the weight vector is represented as the product of a scalar and a vector which allows an efficient weight update in the case of L2 regularization. In the case of sparse feature vectors, the intercept is updated with a smaller learning rate (multiplied by 0.01) to account for the fact that it is updated more frequently. Training examples are picked up sequentially and the learning rate is lowered after each observed example. We adopted the learning rate schedule from

Shalev-Shwartz et al. 2007. For multi-class classification, a “one versus all” approach is used. We use the truncated gradient algorithm proposed by Tsuruoka et al. 2009 for L1 regularization (and the Elastic Net). The code is written in Cython.

### 3.1.6 Nearest Neighbors

`sklearn.neighbors` provides functionality for unsupervised and supervised neighbors-based learning methods. Unsupervised nearest neighbors is the foundation of many other learning methods, notably manifold learning and spectral clustering. Supervised neighbors-based learning comes in two flavors: `classification` for data with discrete labels, and `regression` for data with continuous labels.

The principle behind nearest neighbor methods is to find a predefined number of training samples closest in distance to the new point, and predict the label from these. The number of samples can be a user-defined constant (k-nearest neighbor learning), or vary based on the local density of points (radius-based neighbor learning). The distance can, in general, be any metric measure: standard Euclidean distance is the most common choice. Neighbors-based methods are known as *non-generalizing* machine learning methods, since they simply “remember” all of its training data (possibly transformed into a fast indexing structure such as a `Ball Tree` or `KD Tree`).

Despite its simplicity, nearest neighbors has been successful in a large number of classification and regression problems, including handwritten digits or satellite image scenes. Being a non-parametric method, it is often successful in classification situations where the decision boundary is very irregular.

The classes in `sklearn.neighbors` can handle either Numpy arrays or `scipy.sparse` matrices as input. For dense matrices, a large number of possible distance metrics are supported. For sparse matrices, arbitrary Minkowski metrics are supported for searches.

There are many learning routines which rely on nearest neighbors at their core. One example is `kernel density estimation`, discussed in the `density estimation` section.

#### Unsupervised Nearest Neighbors

`NearestNeighbors` implements unsupervised nearest neighbors learning. It acts as a uniform interface to three different nearest neighbors algorithms: `BallTree`, `KDTree`, and a brute-force algorithm based on routines in `sklearn.metrics.pairwise`. The choice of neighbors search algorithm is controlled through the keyword ‘algorithm’, which must be one of `['auto', 'ball_tree', 'kd_tree', 'brute']`. When the default value `'auto'` is passed, the algorithm attempts to determine the best approach from the training data. For a discussion of the strengths and weaknesses of each option, see `Nearest Neighbor Algorithms`.

**Warning:** Regarding the Nearest Neighbors algorithms, if two neighbors, neighbor  $k + 1$  and  $k$ , have identical distances but different labels, the results will depend on the ordering of the training data.

## Finding the Nearest Neighbors

For the simple task of finding the nearest neighbors between two sets of data, the unsupervised algorithms within `sklearn.neighbors` can be used:

```
>>> from sklearn.neighbors import NearestNeighbors
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> nbrs = NearestNeighbors(n_neighbors=2, algorithm='ball_tree').fit(X)
>>> distances, indices = nbrs.kneighbors(X)
>>> indices
array([[0, 1],
       [1, 0],
       [2, 1],
       [3, 4],
       [4, 3],
       [5, 4]]...)
>>> distances
array([[ 0.          ,  1.          ],
       [ 0.          ,  1.          ],
       [ 0.          ,  1.41421356],
       [ 0.          ,  1.          ],
       [ 0.          ,  1.          ],
       [ 0.          ,  1.41421356]])
```

Because the query set matches the training set, the nearest neighbor of each point is the point itself, at a distance of zero.

It is also possible to efficiently produce a sparse graph showing the connections between neighboring points:

```
>>> nbrs.kneighbors_graph(X).toarray()
array([[ 1.,  1.,  0.,  0.,  0.,  0.],
       [ 1.,  1.,  0.,  0.,  0.,  0.],
       [ 0.,  1.,  1.,  0.,  0.,  0.],
       [ 0.,  0.,  0.,  1.,  1.,  0.],
       [ 0.,  0.,  0.,  1.,  1.,  0.],
       [ 0.,  0.,  0.,  0.,  1.,  1.]])
```

Our dataset is structured such that points nearby in index order are nearby in parameter space, leading to an approximately block-diagonal matrix of K-nearest neighbors. Such a sparse graph is useful in a variety of circumstances which make use of spatial relationships between points for unsupervised learning: in particular, see `sklearn.manifold.Isomap`, `sklearn.manifold.LocallyLinearEmbedding`, and `sklearn.cluster.SpectralClustering`.

## KDTree and BallTree Classes

Alternatively, one can use the `KDTree` or `BallTree` classes directly to find nearest neighbors. This is the functionality wrapped by the `NearestNeighbors` class used above. The Ball Tree and KD Tree have the same interface; we'll show an example of using the KD Tree here:

```
>>> from sklearn.neighbors import KDTree
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> kdt = KDTree(X, leaf_size=30, metric='euclidean')
>>> kdt.query(X, k=2, return_distance=False)
array([[0, 1],
```

```
[1, 0],
[2, 1],
[3, 4],
[4, 3],
[5, 4]]...)
```

Refer to the [KDTree](#) and [BallTree](#) class documentation for more information on the options available for neighbors searches, including specification of query strategies, of various distance metrics, etc. For a list of available metrics, see the documentation of the [DistanceMetric](#) class.

## Nearest Neighbors Classification

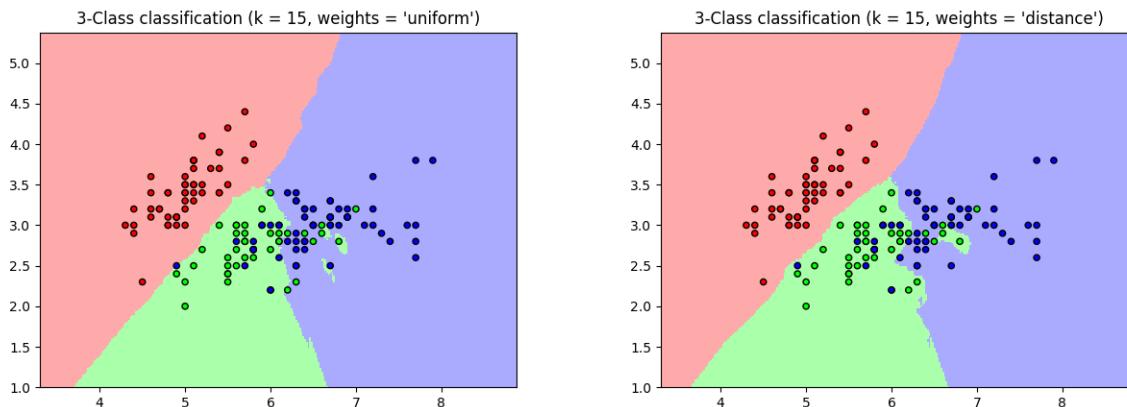

Neighbors-based classification is a type of *instance-based learning* or *non-generalizing learning*: it does not attempt to construct a general internal model, but simply stores instances of the training data. Classification is computed from a simple majority vote of the nearest neighbors of each point: a query point is assigned the data class which has the most representatives within the nearest neighbors of the point.

scikit-learn implements two different nearest neighbors classifiers: [KNeighborsClassifier](#) implements learning based on the  $k$  nearest neighbors of each query point, where  $k$  is an integer value specified by the user. [RadiusNeighborsClassifier](#) implements learning based on the number of neighbors within a fixed radius  $r$  of each training point, where  $r$  is a floating-point value specified by the user.

The  $k$ -neighbors classification in [KNeighborsClassifier](#) is the more commonly used of the two techniques. The optimal choice of the value  $k$  is highly data-dependent: in general a larger  $k$  suppresses the effects of noise, but makes the classification boundaries less distinct.

In cases where the data is not uniformly sampled, radius-based neighbors classification in [RadiusNeighborsClassifier](#) can be a better choice. The user specifies a fixed radius  $r$ , such that points in sparser neighborhoods use fewer nearest neighbors for the classification. For high-dimensional parameter spaces, this method becomes less effective due to the so-called “curse of dimensionality”.

The basic nearest neighbors classification uses uniform weights: that is, the value assigned to a query point is computed from a simple majority vote of the nearest neighbors. Under some circumstances, it is better to weight the neighbors such that nearer neighbors contribute more to the fit. This can be accomplished through the `weights` keyword. The default value, `weights = 'uniform'`, assigns uniform weights to each neighbor. `weights = 'distance'` assigns weights proportional to the inverse of the distance from the query point. Alternatively, a user-defined function of the distance can be supplied which is used to compute the weights.

**Examples:**

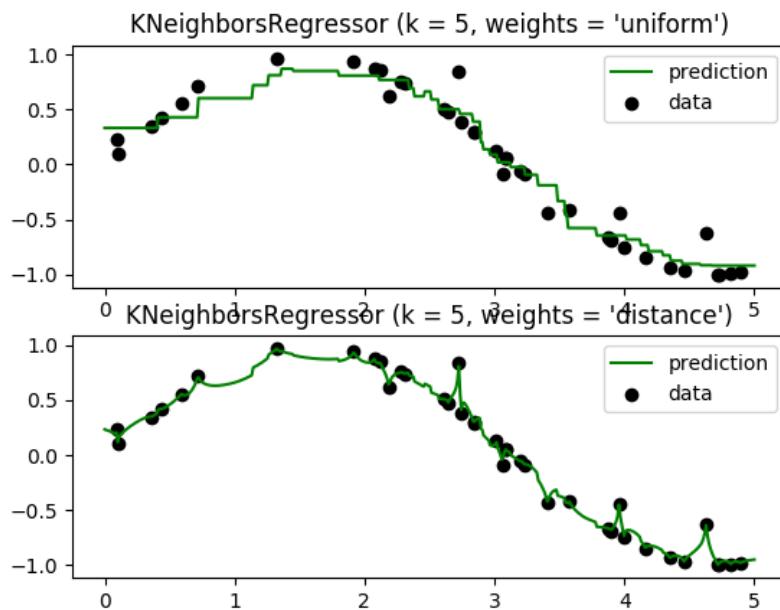

- [Nearest Neighbors Classification](#): an example of classification using nearest neighbors.

## Nearest Neighbors Regression

Neighbors-based regression can be used in cases where the data labels are continuous rather than discrete variables. The label assigned to a query point is computed based the mean of the labels of its nearest neighbors.

scikit-learn implements two different neighbors regressors: `KNeighborsRegressor` implements learning based on the  $k$  nearest neighbors of each query point, where  $k$  is an integer value specified by the user. `RadiusNeighborsRegressor` implements learning based on the neighbors within a fixed radius  $r$  of the query point, where  $r$  is a floating-point value specified by the user.

The basic nearest neighbors regression uses uniform weights: that is, each point in the local neighborhood contributes uniformly to the classification of a query point. Under some circumstances, it can be advantageous to weight points such that nearby points contribute more to the regression than faraway points. This can be accomplished through the `weights` keyword. The default value, `weights = 'uniform'`, assigns equal weights to all points. `weights = 'distance'` assigns weights proportional to the inverse of the distance from the query point. Alternatively, a user-defined function of the distance can be supplied, which will be used to compute the weights.

The use of multi-output nearest neighbors for regression is demonstrated in [Face completion with a multi-output estimators](#). In this example, the inputs  $X$  are the pixels of the upper half of faces and the outputs  $Y$  are the pixels of the lower half of those faces.

**Examples:**

- [Nearest Neighbors regression](#): an example of regression using nearest neighbors.

## Face completion with multi-output estimators

- *Face completion with a multi-output estimators*: an example of multi-output regression using nearest neighbors.

## Nearest Neighbor Algorithms

### Brute Force

Fast computation of nearest neighbors is an active area of research in machine learning. The most naive neighbor search implementation involves the brute-force computation of distances between all pairs of points in the dataset: for  $N$  samples in  $D$  dimensions, this approach scales as  $O[DN^2]$ . Efficient brute-force neighbors searches can be very competitive for small data samples. However, as the number of samples  $N$  grows, the brute-force approach quickly becomes infeasible. In the classes within `sklearn.neighbors`, brute-force neighbors searches are specified using the keyword `algorithm = 'brute'`, and are computed using the routines available in `sklearn.metrics.pairwise`.

### K-D Tree

To address the computational inefficiencies of the brute-force approach, a variety of tree-based data structures have been invented. In general, these structures attempt to reduce the required number of distance calculations by efficiently encoding aggregate distance information for the sample. The basic idea is that if point  $A$  is very distant from point  $B$ , and point  $B$  is very close to point  $C$ , then we know that points  $A$  and  $C$  are very distant, *without having to explicitly calculate their distance*. In this way, the computational cost of a nearest neighbors search can be reduced to  $O[DN \log(N)]$  or better. This is a significant improvement over brute-force for large  $N$ .

An early approach to taking advantage of this aggregate information was the *KD tree* data structure (short for *K-dimensional tree*), which generalizes two-dimensional *Quad-trees* and 3-dimensional *Oct-trees* to an arbitrary number of dimensions. The KD tree is a binary tree structure which recursively partitions the parameter space along the data axes, dividing it into nested orthotopic regions into which data points are filed. The construction of a KD tree is very fast: because partitioning is performed only along the data axes, no  $D$ -dimensional distances need to be computed. Once constructed, the nearest neighbor of a query point can be determined with only  $O[\log(N)]$  distance computations. Though the KD tree approach is very fast for low-dimensional ( $D < 20$ ) neighbors searches, it becomes inefficient as  $D$  grows very large: this is one manifestation of the so-called “curse of dimensionality”. In scikit-learn, KD tree neighbors searches are specified using the keyword `algorithm = 'kd_tree'`, and are computed using the class `KDTree`.

### References:

### Ball Tree

To address the inefficiencies of KD Trees in higher dimensions, the *ball tree* data structure was developed. Where KD trees partition data along Cartesian axes, ball trees partition data in a series of nesting hyper-spheres. This makes tree construction more costly than that of the KD tree, but results in a data structure which can be very efficient on highly-structured data, even in very high dimensions.

A ball tree recursively divides the data into nodes defined by a centroid  $C$  and radius  $r$ , such that each point in the node lies within the hyper-sphere defined by  $r$  and  $C$ . The number of candidate points for a neighbor search is reduced

through use of the *triangle inequality*:

$$|x + y| \leq |x| + |y|$$

With this setup, a single distance calculation between a test point and the centroid is sufficient to determine a lower and upper bound on the distance to all points within the node. Because of the spherical geometry of the ball tree nodes, it can out-perform a *KD-tree* in high dimensions, though the actual performance is highly dependent on the structure of the training data. In scikit-learn, ball-tree-based neighbors searches are specified using the keyword algorithm = 'ball\_tree', and are computed using the class `sklearn.neighbors.BallTree`. Alternatively, the user can work with the `BallTree` class directly.

## Choice of Nearest Neighbors Algorithm

The optimal algorithm for a given dataset is a complicated choice, and depends on a number of factors:

- number of samples  $N$  (i.e. `n_samples`) and dimensionality  $D$  (i.e. `n_features`).
  - *Brute force* query time grows as  $O[DN]$
  - *Ball tree* query time grows as approximately  $O[D \log(N)]$
  - *KD tree* query time changes with  $D$  in a way that is difficult to precisely characterise. For small  $D$  (less than 20 or so) the cost is approximately  $O[D \log(N)]$ , and the KD tree query can be very efficient. For larger  $D$ , the cost increases to nearly  $O[DN]$ , and the overhead due to the tree structure can lead to queries which are slower than brute force.

For small data sets ( $N$  less than 30 or so),  $\log(N)$  is comparable to  $N$ , and brute force algorithms can be more efficient than a tree-based approach. Both `KDTree` and `BallTree` address this through providing a *leaf size* parameter: this controls the number of samples at which a query switches to brute-force. This allows both algorithms to approach the efficiency of a brute-force computation for small  $N$ .

- data structure: *intrinsic dimensionality* of the data and/or *sparsity* of the data. Intrinsic dimensionality refers to the dimension  $d \leq D$  of a manifold on which the data lies, which can be linearly or non-linearly embedded in the parameter space. Sparsity refers to the degree to which the data fills the parameter space (this is to be distinguished from the concept as used in “sparse” matrices. The data matrix may have no zero entries, but the **structure** can still be “sparse” in this sense).
  - *Brute force* query time is unchanged by data structure.
  - *Ball tree* and *KD tree* query times can be greatly influenced by data structure. In general, sparser data with a smaller intrinsic dimensionality leads to faster query times. Because the KD tree internal representation is aligned with the parameter axes, it will not generally show as much improvement as ball tree for arbitrarily structured data.

Datasets used in machine learning tend to be very structured, and are very well-suited for tree-based queries.

- number of neighbors  $k$  requested for a query point.
  - *Brute force* query time is largely unaffected by the value of  $k$
  - *Ball tree* and *KD tree* query time will become slower as  $k$  increases. This is due to two effects: first, a larger  $k$  leads to the necessity to search a larger portion of the parameter space. Second, using  $k > 1$  requires internal queueing of results as the tree is traversed.

As  $k$  becomes large compared to  $N$ , the ability to prune branches in a tree-based query is reduced. In this situation, Brute force queries can be more efficient.

- number of query points. Both the ball tree and the KD Tree require a construction phase. The cost of this construction becomes negligible when amortized over many queries. If only a small number of queries will be performed, however, the construction can make up a significant fraction of the total cost. If very few query points will be required, brute force is better than a tree-based method.

Currently, `algorithm = 'auto'` selects '`kd_tree`' if  $k < N/2$  and the '`effective_metric_`' is in the '`VALID_METRICS`' list of '`kd_tree`'. It selects '`ball_tree`' if  $k < N/2$  and the '`effective_metric_`' is not in the '`VALID_METRICS`' list of '`kd_tree`'. It selects '`brute`' if  $k \geq N/2$ . This choice is based on the assumption that the number of query points is at least the same order as the number of training points, and that `leaf_size` is close to its default value of 30.

### Effect of `leaf_size`

As noted above, for small sample sizes a brute force search can be more efficient than a tree-based query. This fact is accounted for in the ball tree and KD tree by internally switching to brute force searches within leaf nodes. The level of this switch can be specified with the parameter `leaf_size`. This parameter choice has many effects:

**construction time** A larger `leaf_size` leads to a faster tree construction time, because fewer nodes need to be created

**query time** Both a large or small `leaf_size` can lead to suboptimal query cost. For `leaf_size` approaching 1, the overhead involved in traversing nodes can significantly slow query times. For `leaf_size` approaching the size of the training set, queries become essentially brute force. A good compromise between these is `leaf_size = 30`, the default value of the parameter.

**memory** As `leaf_size` increases, the memory required to store a tree structure decreases. This is especially important in the case of ball tree, which stores a  $D$ -dimensional centroid for each node. The required storage space for `BallTree` is approximately  $1 / \text{leaf\_size}$  times the size of the training set.

`leaf_size` is not referenced for brute force queries.

### Nearest Centroid Classifier

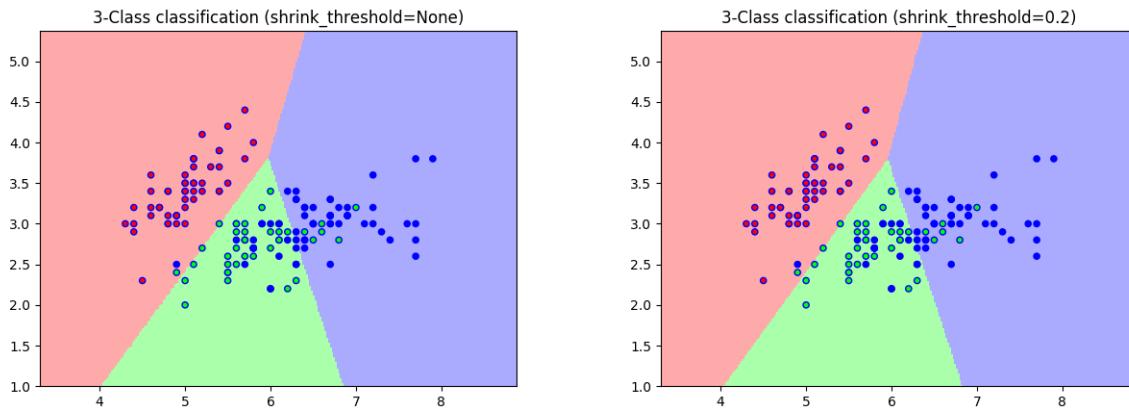

The `NearestCentroid` classifier is a simple algorithm that represents each class by the centroid of its members. In effect, this makes it similar to the label updating phase of the `sklearn.KMeans` algorithm. It also has no parameters to choose, making it a good baseline classifier. It does, however, suffer on non-convex classes, as well as when classes have drastically different variances, as equal variance in all dimensions is assumed. See Linear Discriminant Analysis (`sklearn.discriminant_analysis.LinearDiscriminantAnalysis`) and Quadratic Discriminant Analysis (`sklearn.discriminant_analysis.QuadraticDiscriminantAnalysis`) for more complex methods that do not make this assumption. Usage of the default `NearestCentroid` is simple:

```
>>> from sklearn.neighbors.nearest_centroid import NearestCentroid
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> y = np.array([1, 1, 1, 2, 2, 2])
>>> clf = NearestCentroid()
>>> clf.fit(X, y)
NearestCentroid(metric='euclidean', shrink_threshold=None)
>>> print(clf.predict([-0.8, -1]))
[1]
```

## Nearest Shrunken Centroid

The `NearestCentroid` classifier has a `shrink_threshold` parameter, which implements the nearest shrunken centroid classifier. In effect, the value of each feature for each centroid is divided by the within-class variance of that feature. The feature values are then reduced by `shrink_threshold`. Most notably, if a particular feature value crosses zero, it is set to zero. In effect, this removes the feature from affecting the classification. This is useful, for example, for removing noisy features.

In the example below, using a small shrink threshold increases the accuracy of the model from 0.81 to 0.82.

### Examples:

- *Nearest Centroid Classification*: an example of classification using nearest centroid with different shrink thresholds.

## Approximate Nearest Neighbors

There are many efficient exact nearest neighbor search algorithms for low dimensions  $d$  (approximately 50). However these algorithms perform poorly with respect to space and query time when  $d$  increases. These algorithms are not any better than comparing query point to each point from the database in a high dimension (see *Brute Force*). This is a well-known consequence of the phenomenon called “The Curse of Dimensionality”.

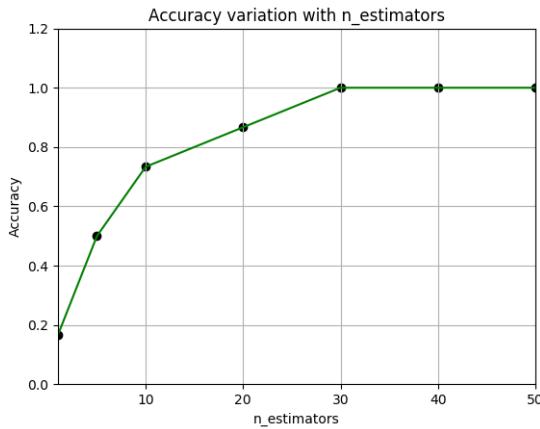

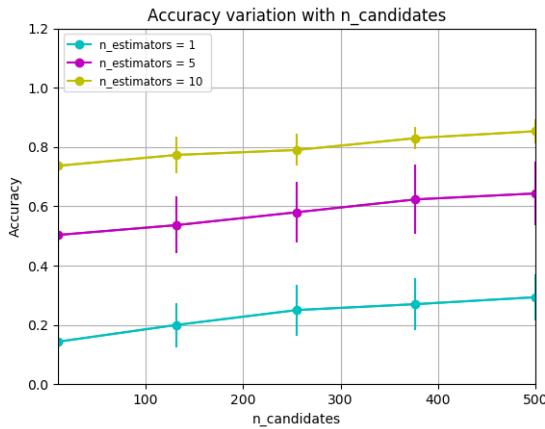

There are certain applications where we do not need the exact nearest neighbors but having a “good guess” would suffice. When answers do not have to be exact, the `LSHForest` class implements an approximate nearest neighbor search. Approximate nearest neighbor search methods have been designed to try to speedup query time with high dimensional data. These techniques are useful when the aim is to characterize the neighborhood rather than identifying the exact neighbors themselves (eg: k-nearest neighbors classification and regression). Some of the most popular approximate nearest neighbor search techniques are locality sensitive hashing, best bin fit and balanced box-decomposition tree based search.

## Locality Sensitive Hashing Forest

The vanilla implementation of locality sensitive hashing has a hyper-parameter that is hard to tune in practice, therefore scikit-learn implements a variant called `LSHForest` that has more reasonable hyperparameters. Both methods use internally random hyperplanes to index the samples into buckets and actual cosine similarities are only computed

for samples that collide with the query hence achieving sublinear scaling. (see [Mathematical description of Locality Sensitive Hashing](#)).

`LSHForest` has two main hyper-parameters: `n_estimators` and `n_candidates`. The accuracy of queries can be controlled using these parameters as demonstrated in the following plots:

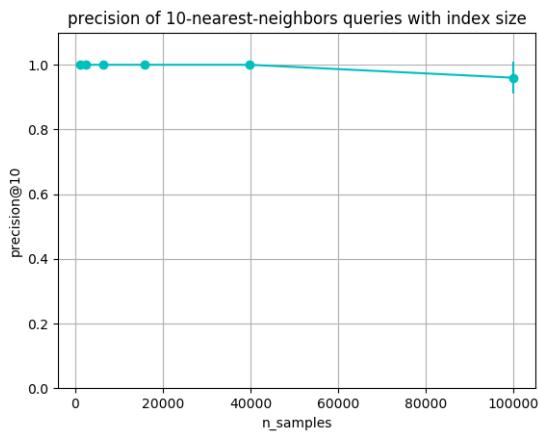

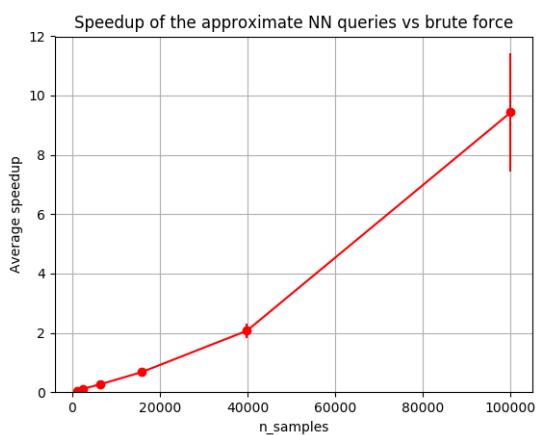

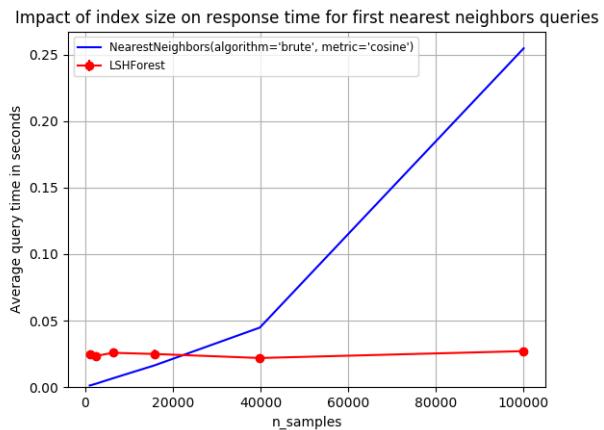

As a rule of thumb, a user can set `n_estimators` to a large enough value (e.g. between 10 and 50) and then adjust `n_candidates` to trade off accuracy for query time.

For small data sets, the brute force method for exact nearest neighbor search can be faster than LSH Forest. However LSH Forest has a sub-linear query time scalability with the index size. The exact break even point where LSH Forest queries become faster than brute force depends on the dimensionality, structure of the dataset, required level of precision, characteristics of the runtime environment such as availability of BLAS optimizations, number of CPU cores and size of the CPU caches. Following graphs depict scalability of LSHForest queries with index size.

For fixed `LSHForest` parameters, the accuracy of queries tends to slowly decrease with larger datasets. The error bars on the previous plots represent standard deviation across different queries.

### Examples:

- [Hyper-parameters of Approximate Nearest Neighbors](#): an example of the behavior of hyperparameters of approximate nearest neighbor search using LSH Forest.

- *Scalability of Approximate Nearest Neighbors*: an example of scalability of approximate nearest neighbor search using LSH Forest.

## Mathematical description of Locality Sensitive Hashing

Locality sensitive hashing (LSH) techniques have been used in many areas where nearest neighbor search is performed in high dimensions. The main concept behind LSH is to hash each data point in the database using multiple (often simple) hash functions to form a digest (also called a *hash*). At this point the probability of collision - where two objects have similar digests - is much higher for the points which are close to each other than that of the distant points. We describe the requirements for a hash function family to be locality sensitive as follows.

A family  $H$  of functions from a domain  $S$  to a range  $U$  is called  $(r, e, p_1, p_2)$ -sensitive, with  $r, e > 0, p_1 > p_2 > 0$ , if for any  $p, q \in S$ , the following conditions hold ( $D$  is the distance function):

- If  $D(p, q) \leq r$  then  $P_H[h(p) = h(q)] \geq p_1$ ,
- If  $D(p, q) > r(1 + e)$  then  $P_H[h(p) = h(q)] \leq p_2$ .

As defined, nearby points within a distance of  $r$  to each other are likely to collide with probability  $p_1$ . In contrast, distant points which are located with the distance more than  $r(1 + e)$  have a small probability of  $p_2$  of collision. Suppose there is a family of LSH function  $H$ . An *LSH index* is built as follows:

1. Choose  $k$  functions  $h_1, h_2, \dots, h_k$  uniformly at random (with replacement) from  $H$ . For any  $p \in S$ , place  $p$  in the bucket with label  $g(p) = (h_1(p), h_2(p), \dots, h_k(p))$ . Observe that if each  $h_i$  outputs one “digit”, each bucket has a  $k$ -digit label.
2. Independently perform step 1  $l$  times to construct  $l$  separate estimators, with hash functions  $g_1, g_2, \dots, g_l$ .

The reason to concatenate hash functions in the step 1 is to decrease the probability of the collision of distant points as much as possible. The probability drops from  $p_2$  to  $p_2^k$  which is negligibly small for large  $k$ . The choice of  $k$  is strongly dependent on the data set size and structure and is therefore hard to tune in practice. There is a side effect of having a large  $k$ ; it has the potential of decreasing the chance of nearby points getting collided. To address this issue, multiple estimators are constructed in step 2.

The requirement to tune  $k$  for a given dataset makes classical LSH cumbersome to use in practice. The LSH Forest variant has been designed to alleviate this requirement by automatically adjusting the number of digits used to hash the samples.

LSH Forest is formulated with prefix trees with each leaf of a tree corresponding to an actual data point in the database. There are  $l$  such trees which compose the forest and they are constructed using independently drawn random sequence of hash functions from  $H$ . In this implementation, “Random Projections” is being used as the LSH technique which is an approximation for the cosine distance. The length of the sequence of hash functions is kept fixed at 32. Moreover, a prefix tree is implemented using sorted arrays and binary search.

There are two phases of tree traversals used in order to answer a query to find the  $m$  nearest neighbors of a point  $q$ . First, a top-down traversal is performed using a binary search to identify the leaf having the longest prefix match (maximum depth) with  $q$ 's label after subjecting  $q$  to the same hash functions.  $M \gg m$  points (total candidates) are extracted from the forest, moving up from the previously found maximum depth towards the root synchronously across all trees in the bottom-up traversal.  $M$  is set to  $cl$  where  $c$ , the number of candidates extracted from each tree, is a constant. Finally, the similarity of each of these  $M$  points against point  $q$  is calculated and the top  $m$  points are returned as the nearest neighbors of  $q$ . Since most of the time in these queries is spent calculating the distances to candidates, the speedup compared to brute force search is approximately  $N/M$ , where  $N$  is the number of points in database.

### 3.1.7 Gaussian Processes

**Gaussian Processes (GP)** are a generic supervised learning method designed to solve *regression* and *probabilistic classification* problems.

The advantages of Gaussian processes are:

- The prediction interpolates the observations (at least for regular kernels).
- The prediction is probabilistic (Gaussian) so that one can compute empirical confidence intervals and decide based on those if one should refit (online fitting, adaptive fitting) the prediction in some region of interest.
- Versatile: different *kernels* can be specified. Common kernels are provided, but it is also possible to specify custom kernels.

The disadvantages of Gaussian processes include:

- They are not sparse, i.e., they use the whole samples/features information to perform the prediction.
- They lose efficiency in high dimensional spaces – namely when the number of features exceeds a few dozens.

#### Gaussian Process Regression (GPR)

The `GaussianProcessRegressor` implements Gaussian processes (GP) for regression purposes. For this, the prior of the GP needs to be specified. The prior mean is assumed to be constant and zero (for `normalize_y=False`) or the training data’s mean (for `normalize_y=True`). The prior’s covariance is specified by a passing a `kernel` object. The hyperparameters of the kernel are optimized during fitting of `GaussianProcessRegressor` by maximizing the log-marginal-likelihood (LML) based on the passed `optimizer`. As the LML may have multiple local optima, the optimizer can be started repeatedly by specifying `n_restarts_optimizer`. The first run is always conducted starting from the initial hyperparameter values of the kernel; subsequent runs are conducted from hyperparameter values that have been chosen randomly from the range of allowed values. If the initial hyperparameters should be kept fixed, `None` can be passed as optimizer.

The noise level in the targets can be specified by passing it via the parameter `alpha`, either globally as a scalar or per datapoint. Note that a moderate noise level can also be helpful for dealing with numeric issues during fitting as it is effectively implemented as Tikhonov regularization, i.e., by adding it to the diagonal of the kernel matrix. An alternative to specifying the noise level explicitly is to include a `WhiteKernel` component into the kernel, which can estimate the global noise level from the data (see example below).

The implementation is based on Algorithm 2.1 of [RW2006]. In addition to the API of standard scikit-learn estimators, `GaussianProcessRegressor`:

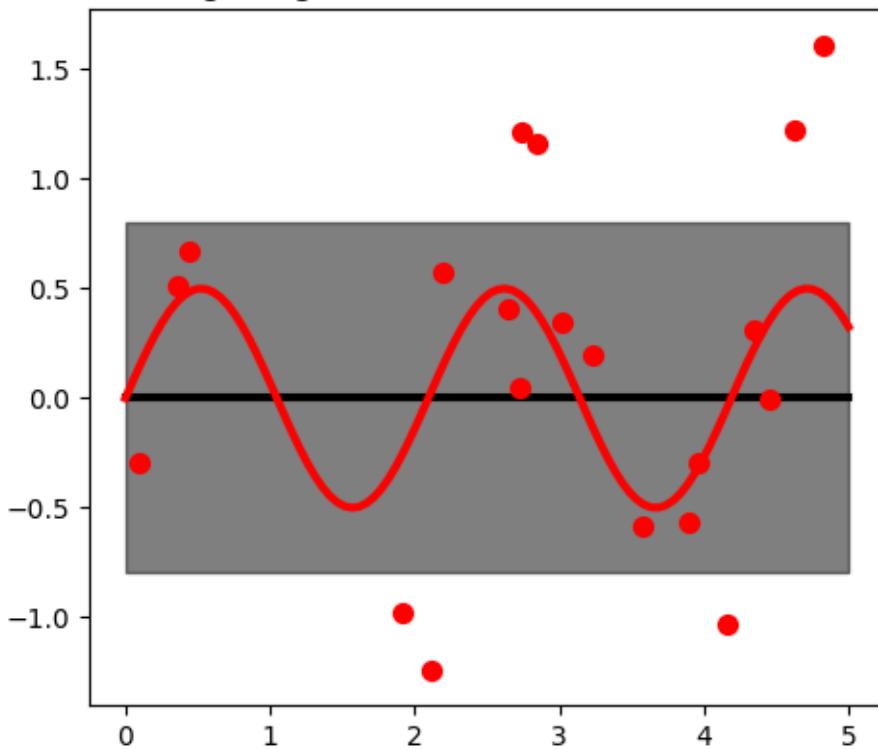

- allows prediction without prior fitting (based on the GP prior)
- provides an additional method `sample_y(X)`, which evaluates samples drawn from the GPR (prior or posterior) at given inputs
- exposes a method `log_marginal_likelihood(theta)`, which can be used externally for other ways of selecting hyperparameters, e.g., via Markov chain Monte Carlo.

## GPR examples

### GPR with noise-level estimation

This example illustrates that GPR with a sum-kernel including a WhiteKernel can estimate the noise level of data. An illustration of the log-marginal-likelihood (LML) landscape shows that there exist two local maxima of LML.

```
Initial: 1**2 * RBF(length_scale=100) + WhiteKernel(noise_level=1)
timum: 0.00316**2 * RBF(length_scale=109) + WhiteKernel(noise_level=0.6
Log-Marginal-Likelihood: -23.872337362
```

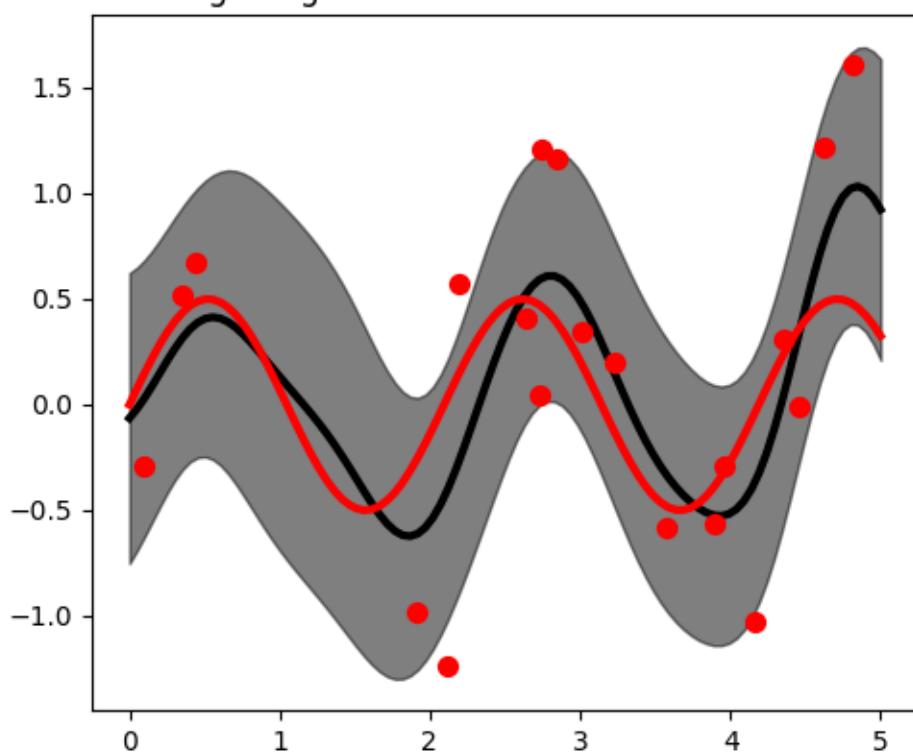

The first corresponds to a model with a high noise level and a large length scale, which explains all variations in the data by noise.

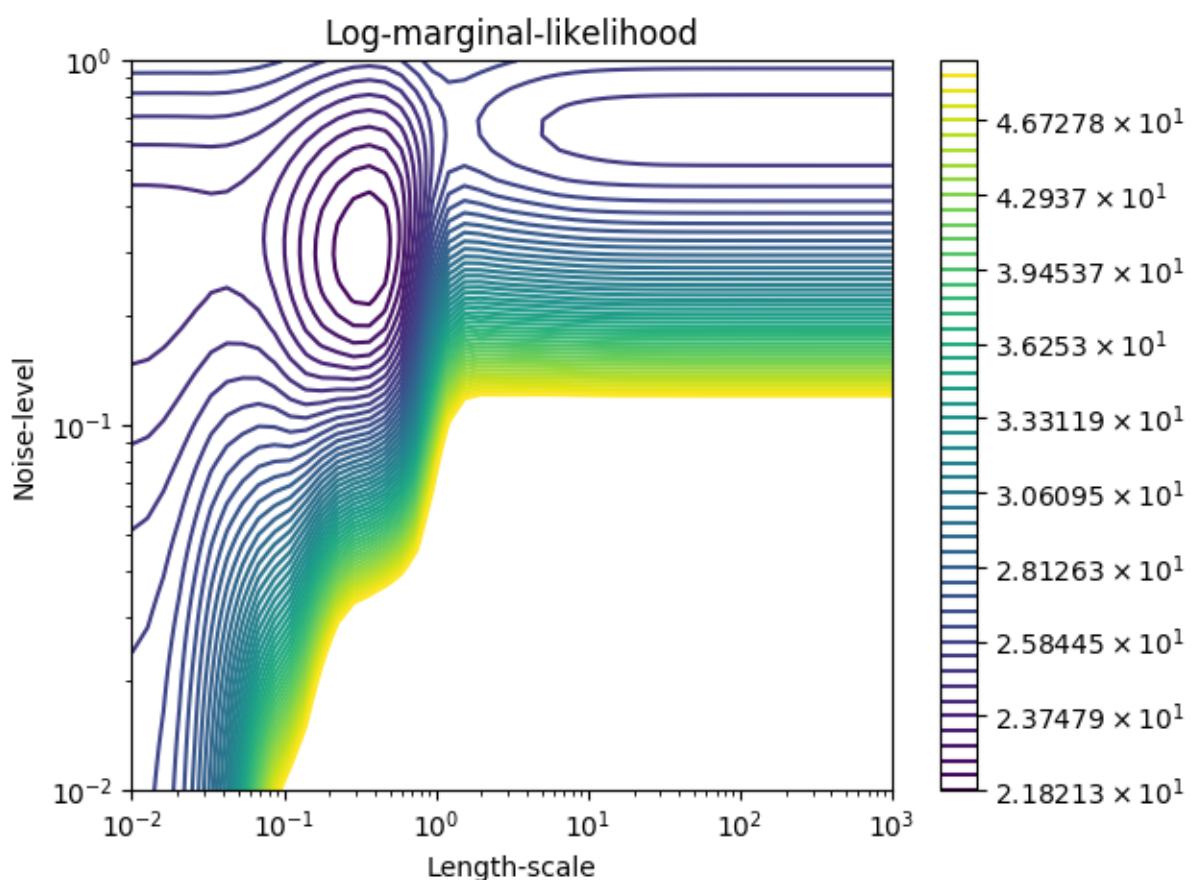

The second one has a smaller noise level and shorter length scale, which explains most of the variation by the noise-free functional relationship. The second model has a higher likelihood; however, depending on the initial value for the hyperparameters, the gradient-based optimization might also converge to the high-noise solution. It is thus important to repeat the optimization several times for different initializations.

### Comparison of GPR and Kernel Ridge Regression

Both kernel ridge regression (KRR) and GPR learn a target function by employing internally the “kernel trick”. KRR learns a linear function in the space induced by the respective kernel which corresponds to a non-linear function in the original space. The linear function in the kernel space is chosen based on the mean-squared error loss with ridge regularization. GPR uses the kernel to define the covariance of a prior distribution over the target functions and uses the observed training data to define a likelihood function. Based on Bayes theorem, a (Gaussian) posterior distribution over target functions is defined, whose mean is used for prediction.

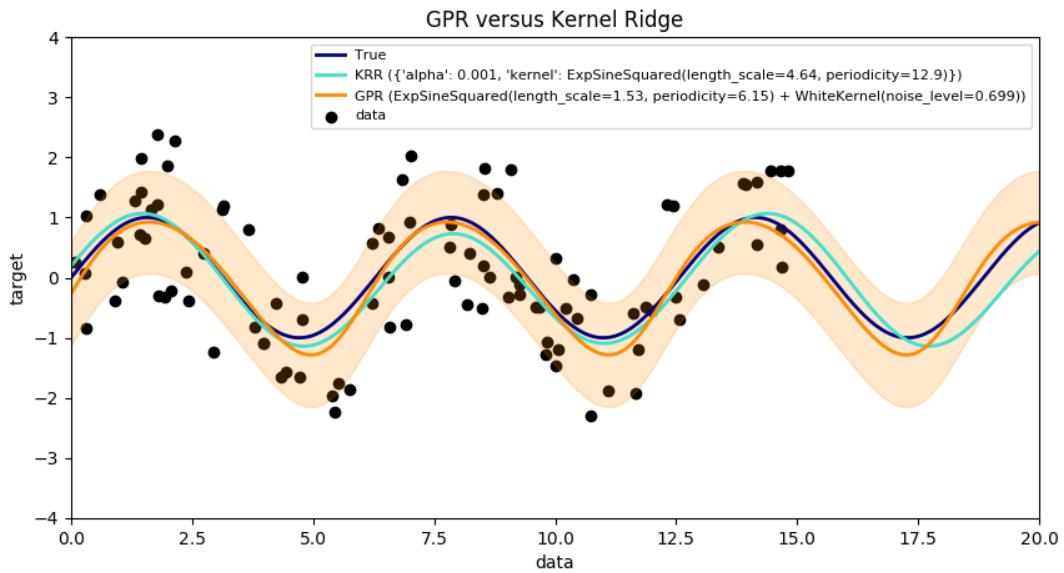

```
Initial: 1**2 * RBF(length_scale=1) + WhiteKernel(noise_level=1e-05)
Optimum: 0.64**2 * RBF(length_scale=0.365) + WhiteKernel(noise_level=0.29
Log-Marginal-Likelihood: -21.8050908902
```

A major difference is that GPR can choose the kernel's hyperparameters based on gradient-ascent on the marginal likelihood function while KRR needs to perform a grid search on a cross-validated loss function (mean-squared error loss). A further difference is that GPR learns a generative, probabilistic model of the target function and can thus provide meaningful confidence intervals and posterior samples along with the predictions while KRR only provides predictions.

The following figure illustrates both methods on an artificial dataset, which consists of a sinusoidal target function and strong noise. The figure compares the learned model of KRR and GPR based on a ExpSineSquared kernel, which is suited for learning periodic functions. The kernel's hyperparameters control the smoothness (length\_scale) and periodicity of the kernel (periodicity). Moreover, the noise level of the data is learned explicitly by GPR by an additional WhiteKernel component in the kernel and by the regularization parameter alpha of KRR.

The figure shows that both methods learn reasonable models of the target function. GPR correctly identifies the periodicity of the function to be roughly  $2 * \pi$  (6.28), while KRR chooses the doubled periodicity  $4 * \pi$ . Besides that, GPR provides reasonable confidence bounds on the prediction which are not available for KRR. A major difference between the two methods is the time required for fitting and predicting: while fitting KRR is fast in principle, the grid-search for hyperparameter optimization scales exponentially with the number of hyperparameters (“curse of dimensionality”). The gradient-based optimization of the parameters in GPR does not suffer from this exponential scaling and is thus considerably faster on this example with 3-dimensional hyperparameter space. The time for predicting is similar; however, generating the variance of the predictive distribution of GPR takes considerable longer than just predicting the mean.

### GPR on Mauna Loa CO2 data

This example is based on Section 5.4.3 of [RW2006]. It illustrates an example of complex kernel engineering and hyperparameter optimization using gradient ascent on the log-marginal-likelihood. The data consists of the monthly average atmospheric CO<sub>2</sub> concentrations (in parts per million by volume (ppmv)) collected at the Mauna Loa Observatory in Hawaii, between 1958 and 1997. The objective is to model the CO<sub>2</sub> concentration as a function of the time t.

The kernel is composed of several terms that are responsible for explaining different properties of the signal:

- a long term, smooth rising trend is to be explained by an RBF kernel. The RBF kernel with a large length-scale

enforces this component to be smooth; it is not enforced that the trend is rising which leaves this choice to the GP. The specific length-scale and the amplitude are free hyperparameters.

- a seasonal component, which is to be explained by the periodic ExpSineSquared kernel with a fixed periodicity of 1 year. The length-scale of this periodic component, controlling its smoothness, is a free parameter. In order to allow decaying away from exact periodicity, the product with an RBF kernel is taken. The length-scale of this RBF component controls the decay time and is a further free parameter.
- smaller, medium term irregularities are to be explained by a RationalQuadratic kernel component, whose length-scale and alpha parameter, which determines the diffuseness of the length-scales, are to be determined. According to [RW2006], these irregularities can better be explained by a RationalQuadratic than an RBF kernel component, probably because it can accommodate several length-scales.
- a “noise” term, consisting of an RBF kernel contribution, which shall explain the correlated noise components such as local weather phenomena, and a WhiteKernel contribution for the white noise. The relative amplitudes and the RBF’s length scale are further free parameters.

Maximizing the log-marginal-likelihood after subtracting the target’s mean yields the following kernel with an LML of -83.214:

```
34.4**2 * RBF(length_scale=41.8)
+ 3.27**2 * RBF(length_scale=180) * ExpSineSquared(length_scale=1.44,
                                                       periodicity=1)
+ 0.446**2 * RationalQuadratic(alpha=17.7, length_scale=0.957)
+ 0.197**2 * RBF(length_scale=0.138) + WhiteKernel(noise_level=0.0336)
```

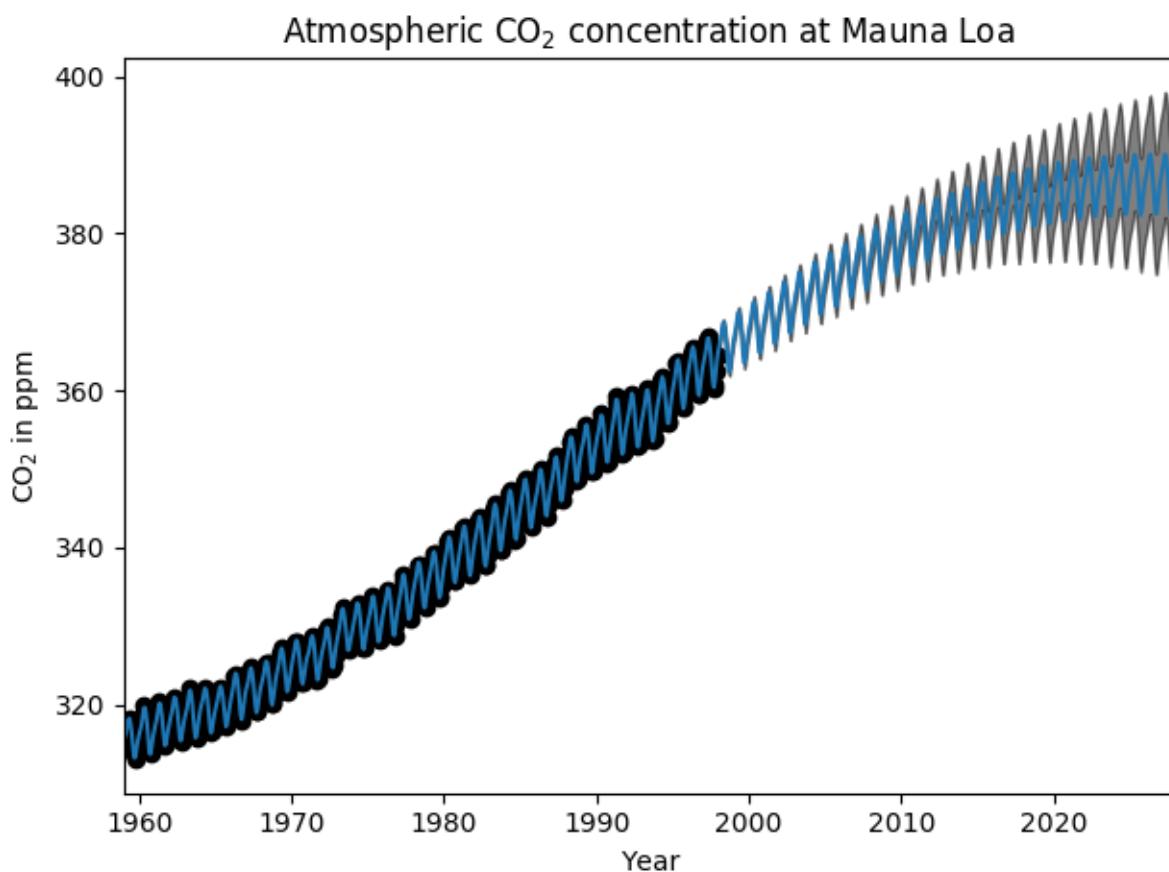

Thus, most of the target signal (34.4ppm) is explained by a long-term rising trend (length-scale 41.8 years). The periodic component has an amplitude of 3.27ppm, a decay time of 180 years and a length-scale of 1.44. The long decay time indicates that we have a locally very close to periodic seasonal component. The correlated noise has an amplitude of 0.197ppm with a length scale of 0.138 years and a white-noise contribution of 0.197ppm. Thus, the overall noise level is very small, indicating that the data can be very well explained by the model. The figure shows also that the model makes very confident predictions until around 2015

## Gaussian Process Classification (GPC)

The `GaussianProcessClassifier` implements Gaussian processes (GP) for classification purposes, more specifically for probabilistic classification, where test predictions take the form of class probabilities. `GaussianProcessClassifier` places a GP prior on a latent function  $f$ , which is then squashed through a link function to obtain the probabilistic classification. The latent function  $f$  is a so-called nuisance function, whose values are not observed and are not relevant by themselves. Its purpose is to allow a convenient formulation of the model, and  $f$  is removed (integrated out) during prediction. `GaussianProcessClassifier` implements the logistic link function, for which the integral cannot be computed analytically but is easily approximated in the binary case.

In contrast to the regression setting, the posterior of the latent function  $f$  is not Gaussian even for a GP prior since a Gaussian likelihood is inappropriate for discrete class labels. Rather, a non-Gaussian likelihood corresponding to the logistic link function (logit) is used. `GaussianProcessClassifier` approximates the non-Gaussian posterior with a Gaussian based on the Laplace approximation. More details can be found in Chapter 3 of [RW2006].

The GP prior mean is assumed to be zero. The prior’s covariance is specified by a passing a `kernel` object. The hyperparameters of the kernel are optimized during fitting of `GaussianProcessRegressor` by maximizing the log-marginal-likelihood (LML) based on the passed `optimizer`. As the LML may have multiple local optima, the optimizer can be started repeatedly by specifying `n_restarts_optimizer`. The first run is always conducted starting from the initial hyperparameter values of the kernel; subsequent runs are conducted from hyperparameter values that have been chosen randomly from the range of allowed values. If the initial hyperparameters should be kept fixed, `None` can be passed as `optimizer`.

`GaussianProcessClassifier` supports multi-class classification by performing either one-versus-rest or one-versus-one based training and prediction. In one-versus-rest, one binary Gaussian process classifier is fitted for each class, which is trained to separate this class from the rest. In “one\_vs\_one”, one binary Gaussian process classifier is fitted for each pair of classes, which is trained to separate these two classes. The predictions of these binary predictors are combined into multi-class predictions. See the section on [multi-class classification](#) for more details.

In the case of Gaussian process classification, “one\_vs\_one” might be computationally cheaper since it has to solve many problems involving only a subset of the whole training set rather than fewer problems on the whole dataset. Since Gaussian process classification scales cubically with the size of the dataset, this might be considerably faster. However, note that “one\_vs\_one” does not support predicting probability estimates but only plain predictions. Moreover, note that `GaussianProcessClassifier` does not (yet) implement a true multi-class Laplace approximation internally, but as discussed above is based on solving several binary classification tasks internally, which are combined using one-versus-rest or one-versus-one.

## GPC examples

### Probabilistic predictions with GPC

This example illustrates the predicted probability of GPC for an RBF kernel with different choices of the hyperparameters. The first figure shows the predicted probability of GPC with arbitrarily chosen hyperparameters and with the hyperparameters corresponding to the maximum log-marginal-likelihood (LML).

While the hyperparameters chosen by optimizing LML have a considerable larger LML, they perform slightly worse according to the log-loss on test data. The figure shows that this is because they exhibit a steep change of the class probabilities at the class boundaries (which is good) but have predicted probabilities close to 0.5 far away from the class boundaries (which is bad). This undesirable effect is caused by the Laplace approximation used internally by GPC.

The second figure shows the log-marginal-likelihood for different choices of the kernel’s hyperparameters, highlighting the two choices of the hyperparameters used in the first figure by black dots.

### Illustration of GPC on the XOR dataset

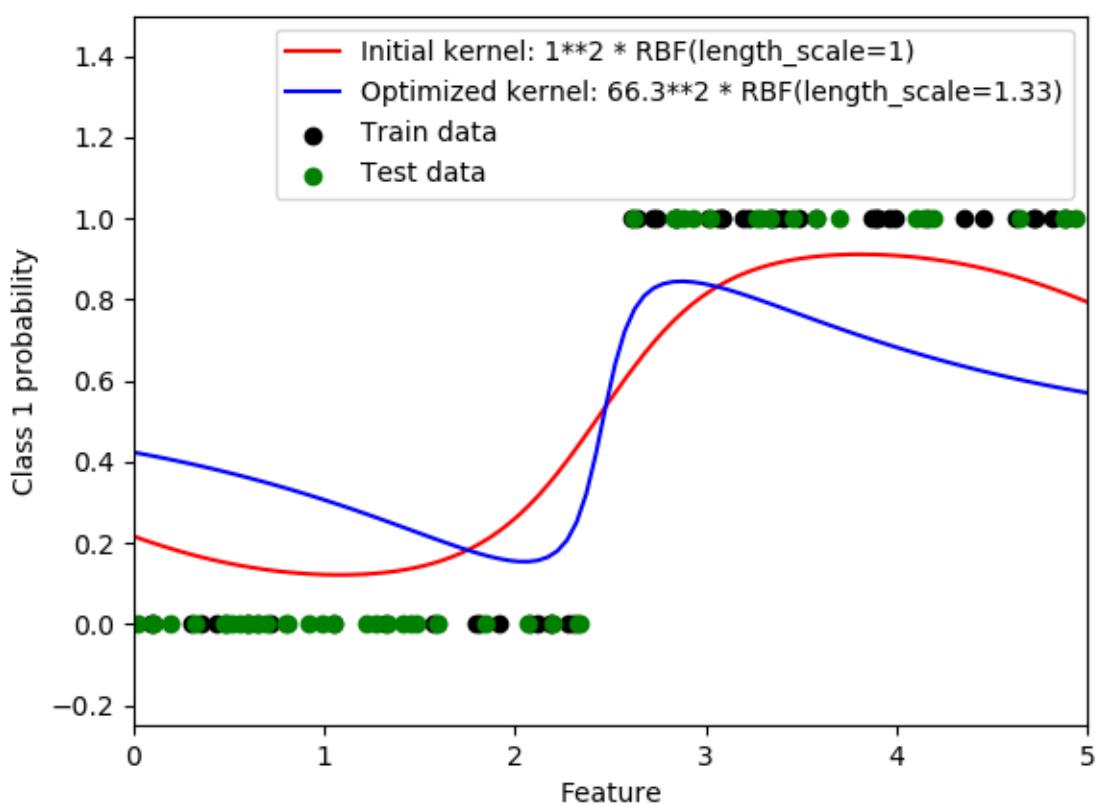

This example illustrates GPC on XOR data. Compared are a stationary, isotropic kernel (`RBF`) and a non-stationary kernel (`DotProduct`). On this particular dataset, the `DotProduct` kernel obtains considerably better results because the class-boundaries are linear and coincide with the coordinate axes. In practice, however, stationary kernels such as `RBF` often obtain better results.

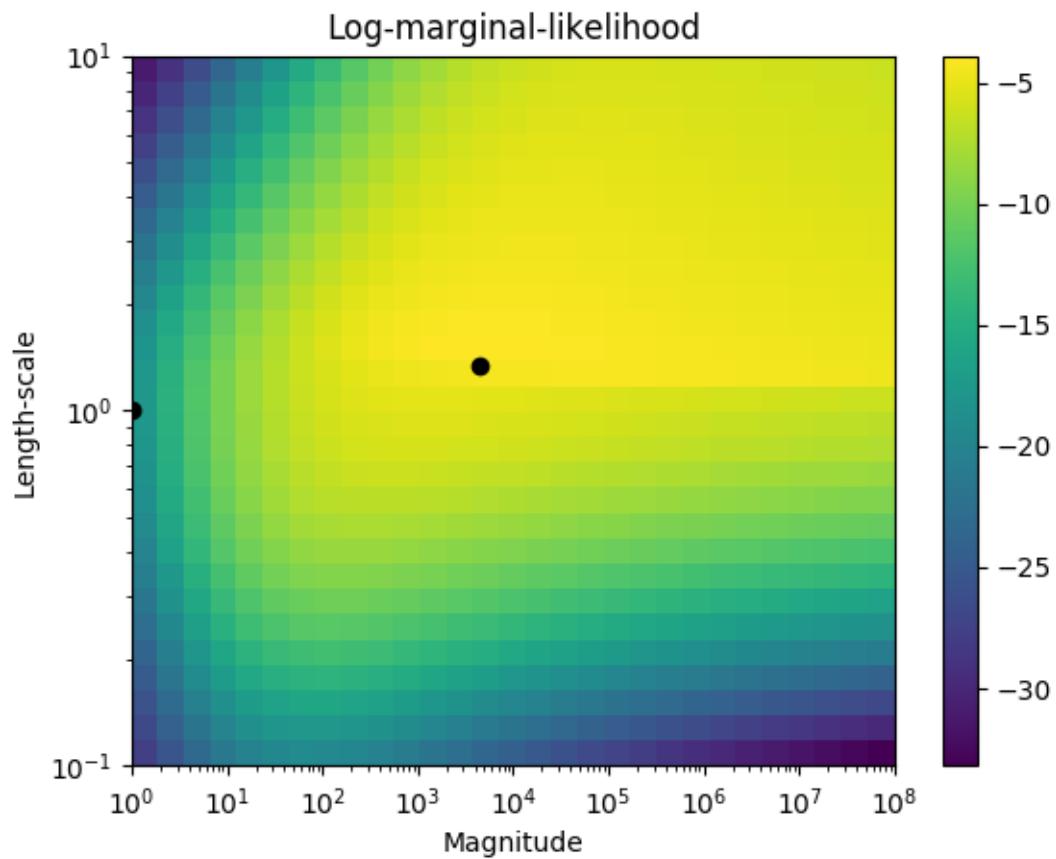

### Gaussian process classification (GPC) on iris dataset

This example illustrates the predicted probability of GPC for an isotropic and anisotropic RBF kernel on a two-dimensional version for the iris-dataset. This illustrates the applicability of GPC to non-binary classification. The anisotropic RBF kernel obtains slightly higher log-marginal-likelihood by assigning different length-scales to the two feature dimensions.

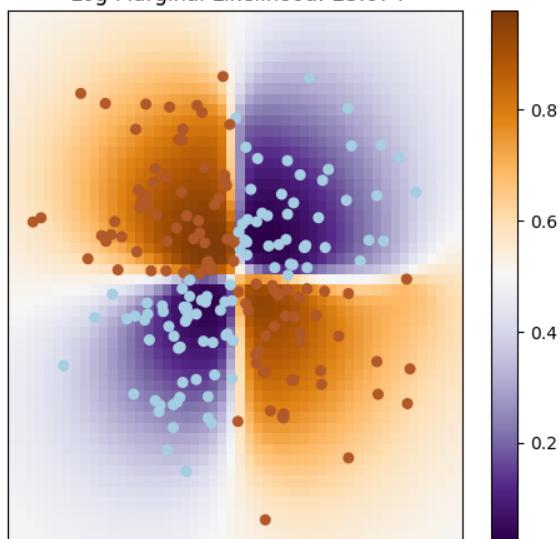

### Kernels for Gaussian Processes

Kernels (also called “covariance functions” in the context of GPs) are a crucial ingredient of GPs which determine the shape of prior and posterior of the GP. They encode the assumptions on the function being learned by defining the “similarity” of two datapoints combined with the assumption that similar datapoints should have similar target values. Two categories of kernels can be distinguished: stationary kernels depend only on the distance of two datapoints and not on their absolute values  $k(x_i, x_j) = k(d(x_i, x_j))$  and are thus invariant to translations in the input space,

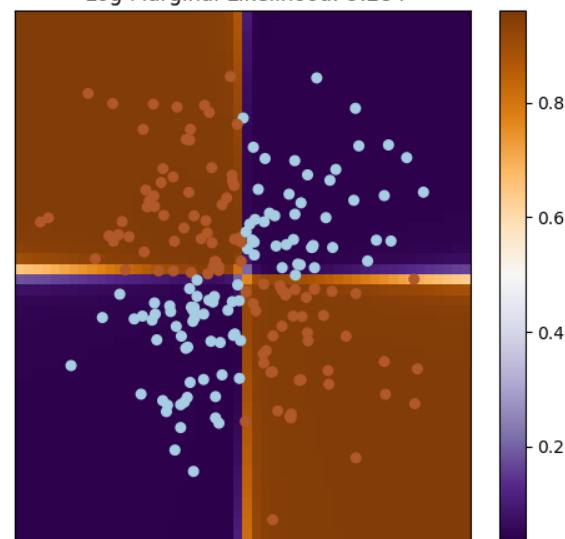

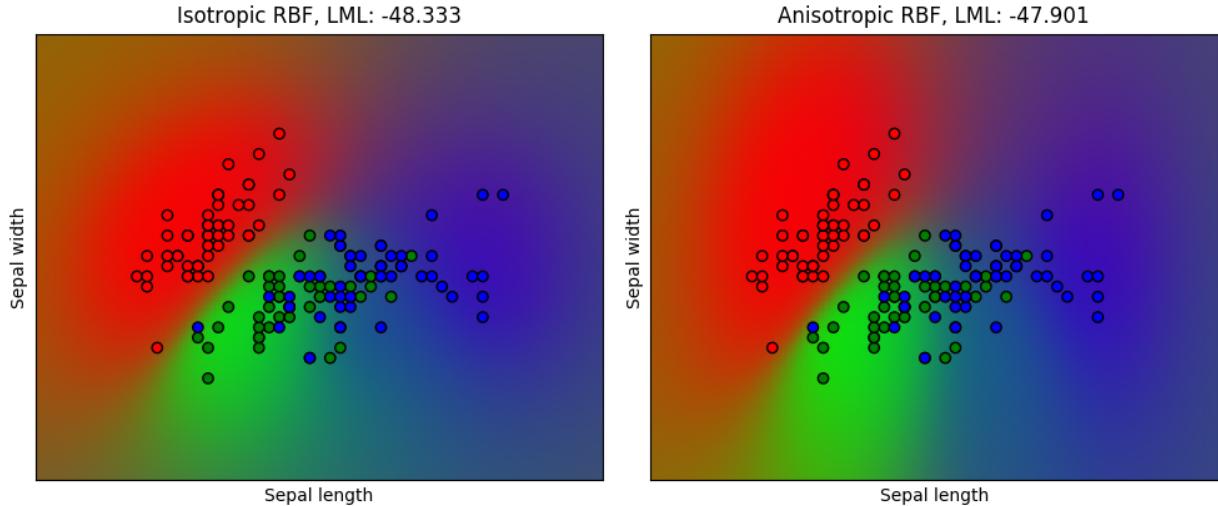

$316^{**2} * \text{RBF}(\text{length\_scale}=1.25)$   
Log-Marginal-Likelihood:-23.674

$316^{**2} * \text{DotProduct}(\sigma_0=0.0104)^{** 2}$   
Log-Marginal-Likelihood:-9.284

while non-stationary kernels depend also on the specific values of the datapoints. Stationary kernels can further be subdivided into isotropic and anisotropic kernels, where isotropic kernels are also invariant to rotations in the input space. For more details, we refer to Chapter 4 of [RW2006].

## Gaussian Process Kernel API

The main usage of a [Kernel](#) is to compute the GP’s covariance between datapoints. For this, the method `__call__` of the kernel can be called. This method can either be used to compute the “auto-covariance” of all pairs of datapoints in a 2d array `X`, or the “cross-covariance” of all combinations of datapoints of a 2d array `X` with datapoints in a 2d array `Y`. The following identity holds true for all kernels `k` (except for the [WhiteKernel](#)): `k(X) == K(X, Y=X)`

If only the diagonal of the auto-covariance is being used, the method `diag()` of a kernel can be called, which is more computationally efficient than the equivalent call to `__call__`: `np.diag(k(X, X)) == k.diag(X)`

Kernels are parameterized by a vector  $\theta$  of hyperparameters. These hyperparameters can for instance control lengthscales or periodicity of a kernel (see below). All kernels support computing analytic gradients of the kernel’s auto-covariance with respect to  $\theta$  via setting `eval_gradient=True` in the `__call__` method. This gradient is used by the Gaussian process (both regressor and classifier) in computing the gradient of the log-marginal-likelihood, which in turn is used to determine the value of  $\theta$ , which maximizes the log-marginal-likelihood, via gradient ascent. For each hyperparameter, the initial value and the bounds need to be specified when creating an instance of the kernel. The current value of  $\theta$  can be get and set via the property `theta` of the kernel object. Moreover, the bounds of the hyperparameters can be accessed by the property `bounds` of the kernel. Note that both properties (`theta` and `bounds`) return log-transformed values of the internally used values since those are typically more amenable to gradient-based optimization. The specification of each hyperparameter is stored in the form of an instance of [Hyperparameter](#) in the respective kernel. Note that a kernel using a hyperparameter with name “`x`” must have the attributes `self.x` and `self.x_bounds`.

The abstract base class for all kernels is [Kernel](#). `Kernel` implements a similar interface as `Estimator`, providing the methods `get_params()`, `set_params()`, and `clone()`. This allows setting kernel values also via meta-estimators such as `Pipeline` or `GridSearch`. Note that due to the nested structure of kernels (by applying kernel operators, see below), the names of kernel parameters might become relatively complicated. In general, for a binary kernel operator, parameters of the left operand are prefixed with `k1__` and parameters of the right operand with `k2__`. An additional convenience method is `clone_with_theta(theta)`, which returns a cloned version of the kernel

but with the hyperparameters set to theta. An illustrative example:

```
>>> from sklearn.gaussian_process.kernels import ConstantKernel, RBF
>>> kernel = ConstantKernel(constant_value=1.0, constant_value_bounds=(0.0, 10.0)) *
... RBF(length_scale=0.5, length_scale_bounds=(0.0, 10.0)) + RBF(length_scale=2.0,_
... length_scale_bounds=(0.0, 10.0))
>>> for hyperparameter in kernel.hyperparameters: print(hyperparameter)
Hyperparameter(name='k1__k1__constant_value', value_type='numeric', bounds=array([[ 0.,
... 10.]]), n_elements=1, fixed=False)
Hyperparameter(name='k1__k2__length_scale', value_type='numeric', bounds=array([[ 0.,
... 10.]]), n_elements=1, fixed=False)
Hyperparameter(name='k2__length_scale', value_type='numeric', bounds=array([[ 0.,
... 10.]]), n_elements=1, fixed=False)
>>> params = kernel.get_params()
>>> for key in sorted(params): print("%s : %s" % (key, params[key]))
k1 : 1**2 * RBF(length_scale=0.5)
k1__k1 : 1**2
k1__k1__constant_value : 1.0
k1__k1__constant_value_bounds : (0.0, 10.0)
k1__k2 : RBF(length_scale=0.5)
k1__k2__length_scale : 0.5
k1__k2__length_scale_bounds : (0.0, 10.0)
k2 : RBF(length_scale=2)
k2__length_scale : 2.0
k2__length_scale_bounds : (0.0, 10.0)
>>> print(kernel.theta) # Note: log-transformed
[ 0.          -0.69314718  0.69314718]
>>> print(kernel.bounds) # Note: log-transformed
[[      -inf  2.30258509]
 [      -inf  2.30258509]
 [      -inf  2.30258509]]
```

All Gaussian process kernels are interoperable with `sklearn.metrics.pairwise` and vice versa: instances of subclasses of `Kernel` can be passed as `metric` to `pairwise_kernels` from `sklearn.metrics.pairwise`. Moreover, kernel functions from `pairwise` can be used as GP kernels by using the wrapper class `PairwiseKernel`. The only caveat is that the gradient of the hyperparameters is not analytic but numeric and all those kernels support only isotropic distances. The parameter `gamma` is considered to be a hyperparameter and may be optimized. The other kernel parameters are set directly at initialization and are kept fixed.

## Basic kernels

The `ConstantKernel` kernel can be used as part of a `Product` kernel where it scales the magnitude of the other factor (kernel) or as part of a `Sum` kernel, where it modifies the mean of the Gaussian process. It depends on a parameter `constant_value`. It is defined as:

$$k(x_i, x_j) = \text{constant\_value} \quad \forall x_1, x_2$$

The main use-case of the `WhiteKernel` kernel is as part of a sum-kernel where it explains the noise-component of the signal. Tuning its parameter `noise_level` corresponds to estimating the noise-level. It is defined as:

$$k(x_i, x_j) = \text{noise\_level} \text{ if } x_i == x_j \text{ else } 0$$

## Kernel operators

Kernel operators take one or two base kernels and combine them into a new kernel. The `Sum` kernel takes two kernels `k1` and `k2` and combines them via  $k_{\text{sum}}(X, Y) = k1(X, Y) + k2(X, Y)$ . The `Product` kernel takes two kernels `k1`

and  $k2$  and combines them via  $k_{product}(X, Y) = k1(X, Y) * k2(X, Y)$ . The *Exponentiation* kernel takes one base kernel and a scalar parameter  $exponent$  and combines them via  $k_{exp}(X, Y) = k(X, Y)^{exponent}$ .

### Radial-basis function (RBF) kernel

The *RBF* kernel is a stationary kernel. It is also known as the “squared exponential” kernel. It is parameterized by a length-scale parameter  $l > 0$ , which can either be a scalar (isotropic variant of the kernel) or a vector with the same number of dimensions as the inputs  $x$  (anisotropic variant of the kernel). The kernel is given by:

$$k(x_i, x_j) = \exp\left(-\frac{1}{2}d(x_i/l, x_j/l)^2\right)$$

This kernel is infinitely differentiable, which implies that GPs with this kernel as covariance function have mean square derivatives of all orders, and are thus very smooth. The prior and posterior of a GP resulting from an RBF kernel are shown in the following figure:

### Matérn kernel

The *Matern* kernel is a stationary kernel and a generalization of the *RBF* kernel. It has an additional parameter  $\nu$  which controls the smoothness of the resulting function. It is parameterized by a length-scale parameter  $l > 0$ , which can either be a scalar (isotropic variant of the kernel) or a vector with the same number of dimensions as the inputs  $x$  (anisotropic variant of the kernel). The kernel is given by:

$$k(x_i, x_j) = \sigma^2 \frac{1}{\Gamma(\nu)2^{\nu-1}} \left( \gamma \sqrt{2\nu} d(x_i/l, x_j/l) \right)^\nu K_\nu \left( \gamma \sqrt{2\nu} d(x_i/l, x_j/l) \right),$$

As  $\nu \rightarrow \infty$ , the Matérn kernel converges to the RBF kernel. When  $\nu = 1/2$ , the Matérn kernel becomes identical to the absolute exponential kernel, i.e.,

$$k(x_i, x_j) = \sigma^2 \exp\left(-\gamma d(x_i/l, x_j/l)\right) \quad \nu = \frac{1}{2}$$

In particular,  $\nu = 3/2$ :

$$k(x_i, x_j) = \sigma^2 \left( 1 + \gamma \sqrt{3} d(x_i/l, x_j/l) \right) \exp\left(-\gamma \sqrt{3} d(x_i/l, x_j/l)\right) \quad \nu = \frac{3}{2}$$

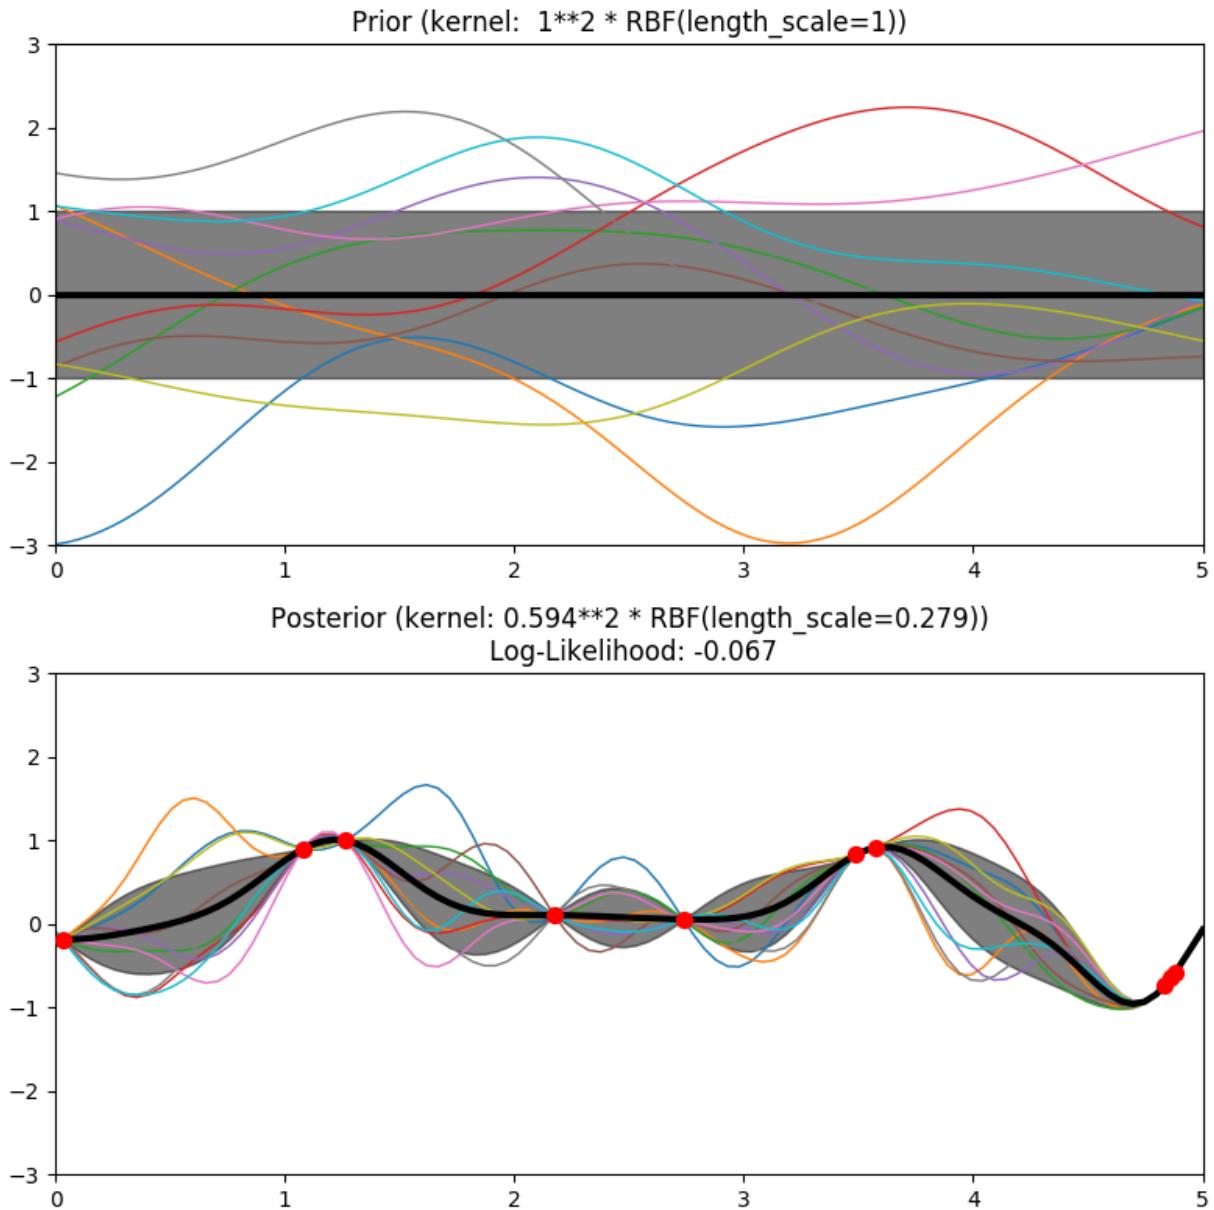

and  $\nu = 5/2$ :

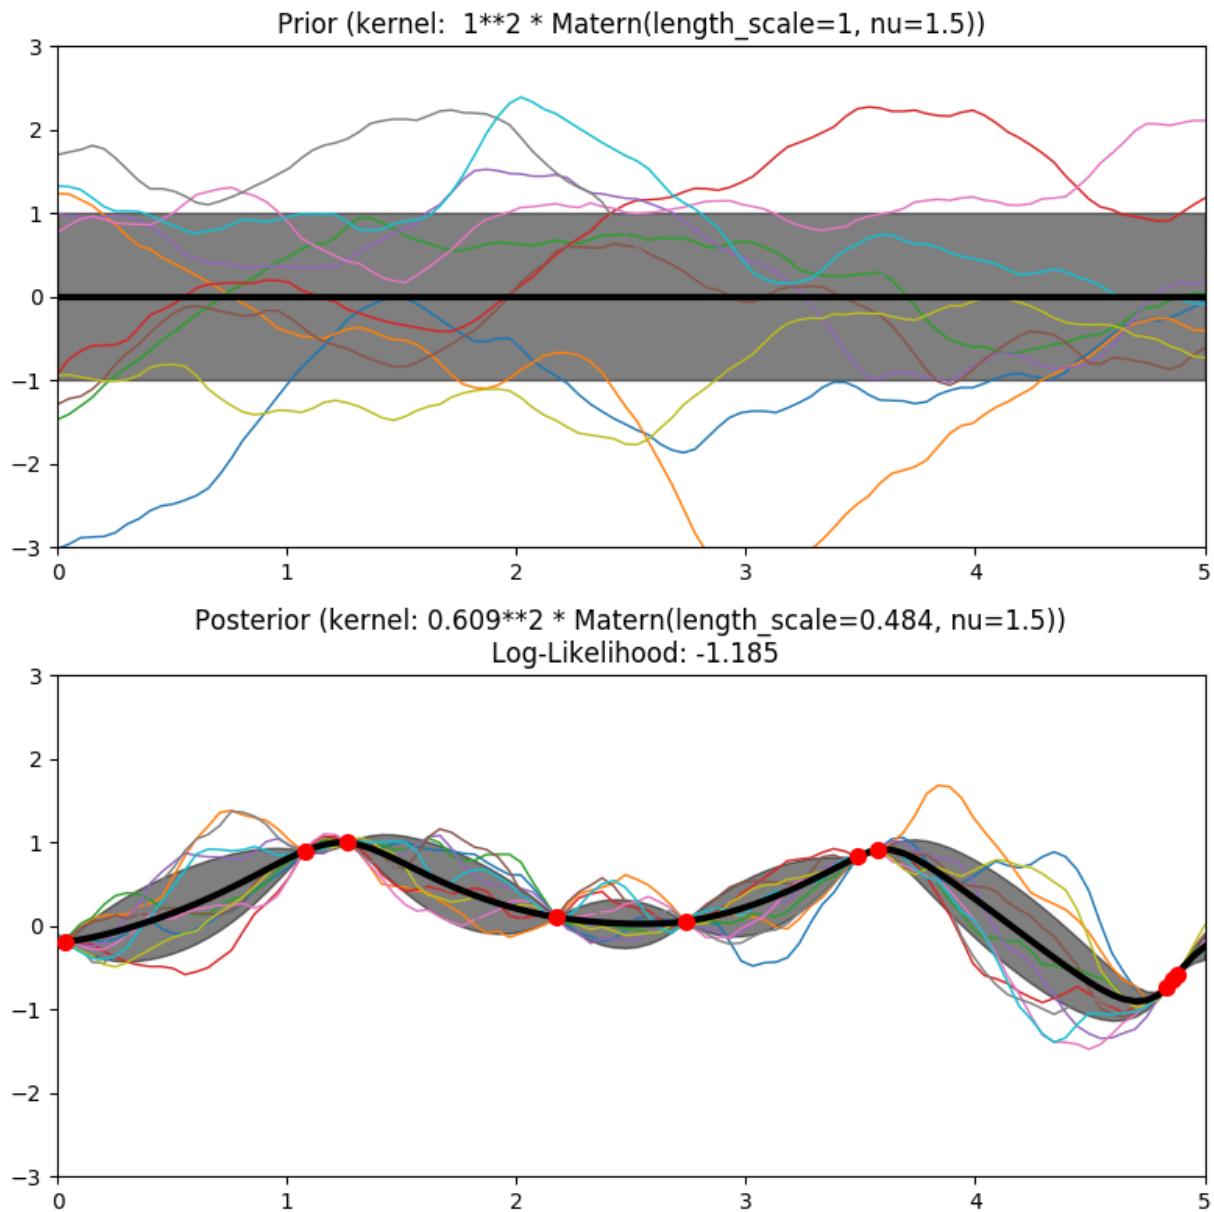

$$k(x_i, x_j) = \sigma^2 \left( 1 + \gamma \sqrt{5} d(x_i/l, x_j/l) + \frac{5}{3} \gamma^2 d(x_i/l, x_j/l)^2 \right) \exp\left(-\gamma \sqrt{5} d(x_i/l, x_j/l)\right) \quad \nu = \frac{5}{2}$$

are popular choices for learning functions that are not infinitely differentiable (as assumed by the RBF kernel) but at least once ( $\nu = 3/2$ ) or twice differentiable ( $\nu = 5/2$ ).

The flexibility of controlling the smoothness of the learned function via  $\nu$  allows adapting to the properties of the true underlying functional relation. The prior and posterior of a GP resulting from a Matérn kernel are shown in the following figure:

See [RW2006], pp84 for further details regarding the different variants of the Matérn kernel.

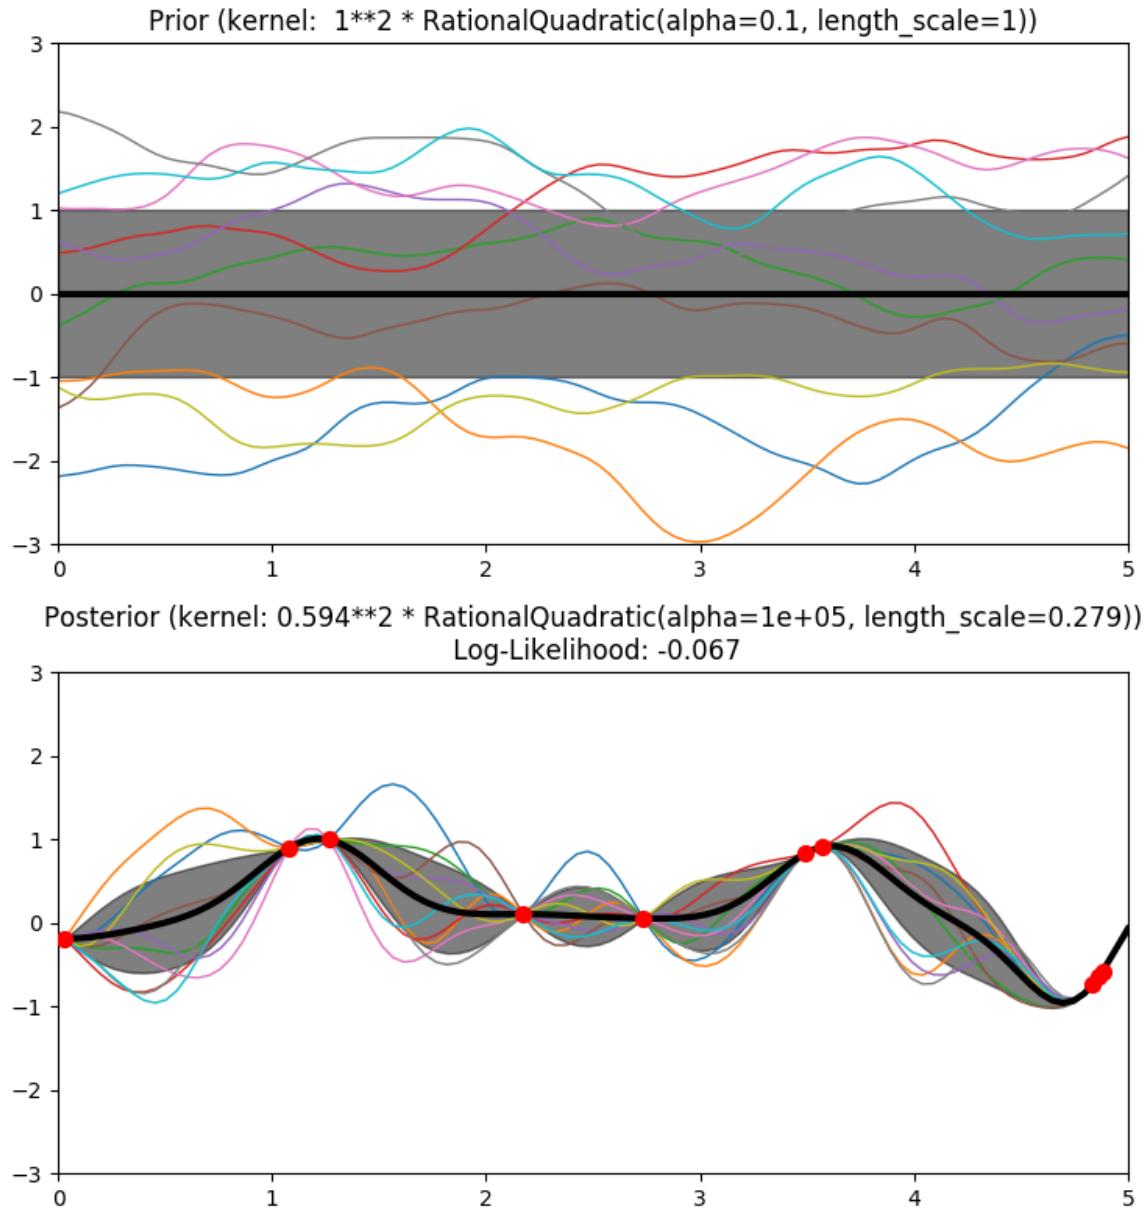

## Rational quadratic kernel

The `RationalQuadratic` kernel can be seen as a scale mixture (an infinite sum) of `RBF` kernels with different characteristic length-scales. It is parameterized by a length-scale parameter  $l > 0$  and a scale mixture parameter  $\alpha > 0$ . Only the isotropic variant where  $l$  is a scalar is supported at the moment. The kernel is given by:

$$k(x_i, x_j) = \left(1 + \frac{d(x_i, x_j)^2}{2\alpha l^2}\right)^{-\alpha}$$

The prior and posterior of a GP resulting from an RBF kernel are shown in the following figure:

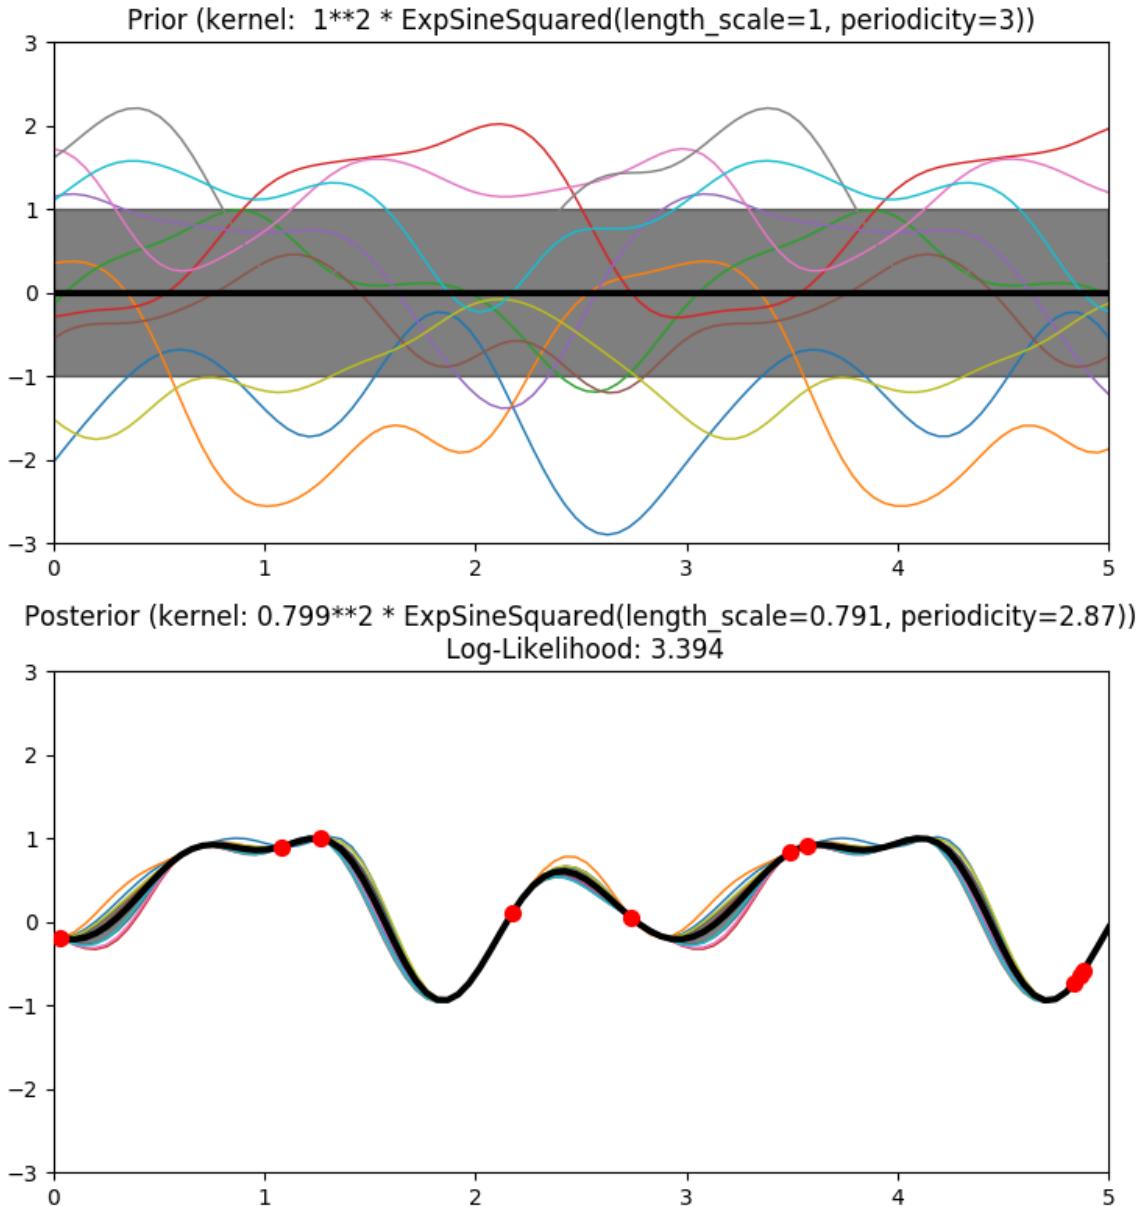

## Exp-Sine-Squared kernel

The `ExpSineSquared` kernel allows modeling periodic functions. It is parameterized by a length-scale parameter  $l > 0$  and a periodicity parameter  $p > 0$ . Only the isotropic variant where  $l$  is a scalar is supported at the moment. The kernel is given by:

$$k(x_i, x_j) = \exp\left(-2(\sin(\pi/p * d(x_i, x_j))/l)^2\right)$$

The prior and posterior of a GP resulting from an ExpSineSquared kernel are shown in the following figure:

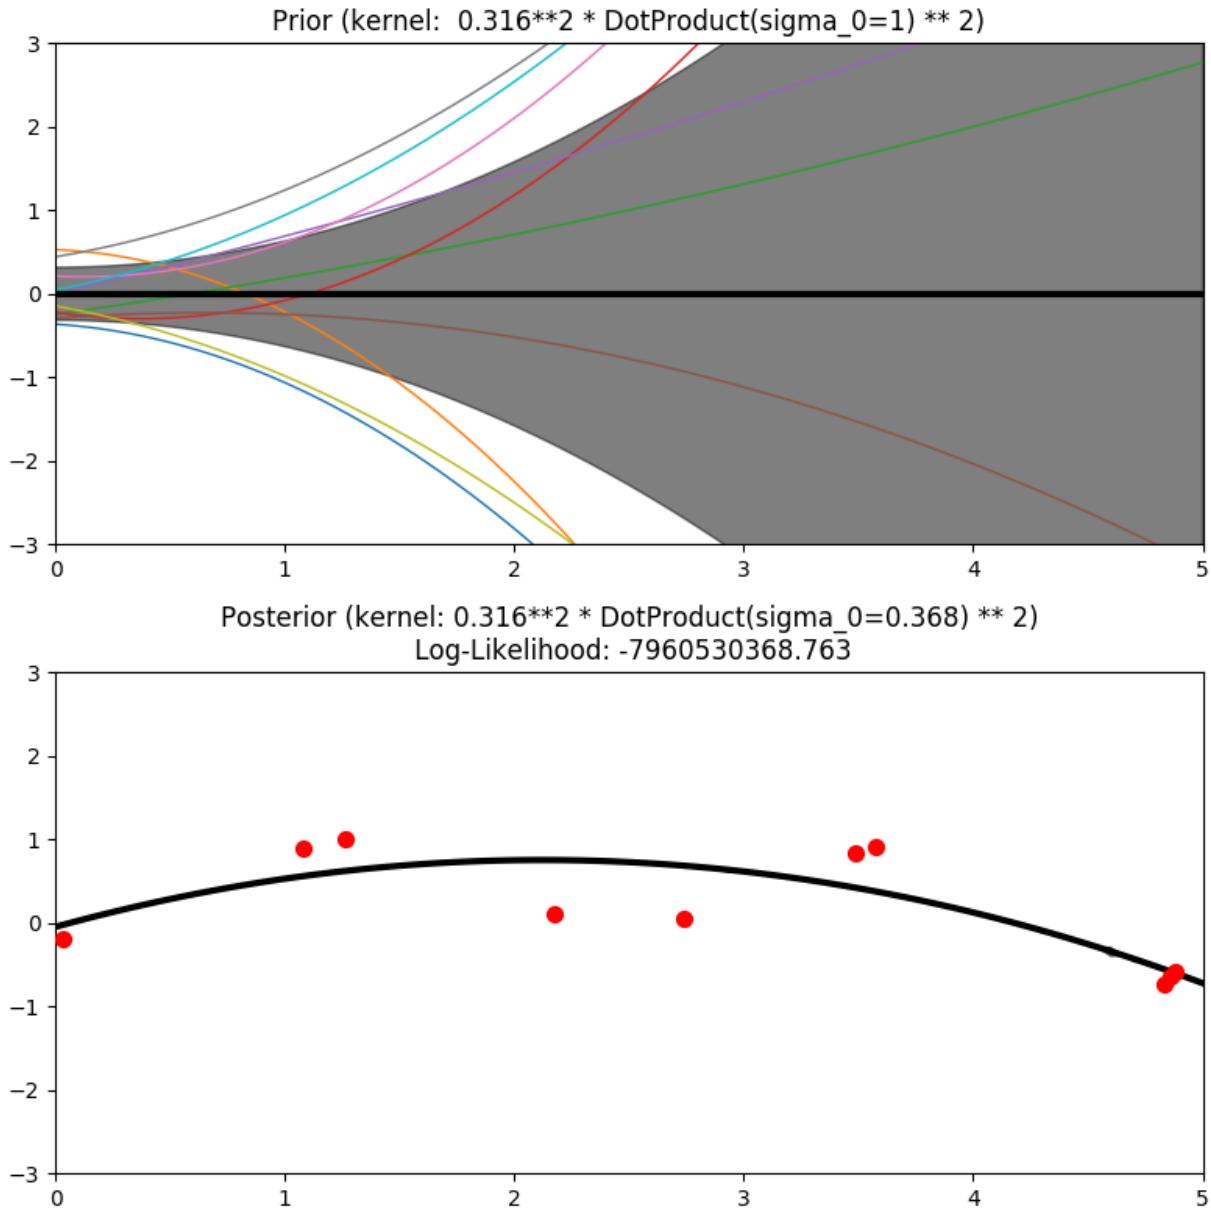

## Dot-Product kernel

The [DotProduct](#) kernel is non-stationary and can be obtained from linear regression by putting  $N(0, 1)$  priors on the coefficients of  $x_d (d = 1, \dots, D)$  and a prior of  $N(0, \sigma_0^2)$  on the bias. The [DotProduct](#) kernel is invariant to a rotation of the coordinates about the origin, but not translations. It is parameterized by a parameter  $\sigma_0^2$ . For  $\sigma_0^2 = 0$ , the kernel is called the homogeneous linear kernel, otherwise it is inhomogeneous. The kernel is given by

$$k(x_i, x_j) = \sigma_0^2 + x_i \cdot x_j$$

The [DotProduct](#) kernel is commonly combined with exponentiation. An example with exponent 2 is shown in the following figure:

## Legacy Gaussian Processes

In this section, the implementation of Gaussian processes used in scikit-learn until release 0.16.1 is described. Note that this implementation is deprecated and will be removed in version 0.18.

### An introductory regression example

Say we want to surrogate the function  $g(x) = x \sin(x)$ . To do so, the function is evaluated onto a design of experiments. Then, we define a GaussianProcess model whose regression and correlation models might be specified using additional kwargs, and ask for the model to be fitted to the data. Depending on the number of parameters provided at instantiation, the fitting procedure may recourse to maximum likelihood estimation for the parameters or alternatively it uses the given parameters.

```
>>> import numpy as np
>>> from sklearn import gaussian_process
>>> def f(x):
...     return x * np.sin(x)
>>> X = np.atleast_2d([1., 3., 5., 6., 7., 8.]).T
>>> y = f(X).ravel()
>>> x = np.atleast_2d(np.linspace(0, 10, 1000)).T
>>> gp = gaussian_process.GaussianProcess(theta0=1e-2, thetaL=1e-4, thetaU=1e-1)
>>> gp.fit(X, y)
GaussianProcess(beta0=None, corr=<function squared_exponential at 0x...>,
    normalize=True, nugget=array(2.22...-15),
    optimizer='fmin_cobyla', random_start=1, random_state=...
    regr=<function constant at 0x...>, storage_mode='full',
    theta0=array([[ 0.01]]), thetaL=array([[ 0.0001]]),
    thetaU=array([[ 0.1]]), verbose=False)
>>> y_pred, sigma2_pred = gp.predict(x, eval_MSE=True)
```

## Fitting Noisy Data

When the data to be fit includes noise, the Gaussian process model can be used by specifying the variance of the noise for each point. `GaussianProcess` takes a parameter `nugget` which is added to the diagonal of the correlation matrix between training points: in general this is a type of Tikhonov regularization. In the special case of a squared-exponential correlation function, this normalization is equivalent to specifying a fractional variance in the input. That is

$$\text{nugget}_i = \left[ \frac{\sigma_i}{y_i} \right]^2$$

With `nugget` and `corr` properly set, Gaussian Processes can be used to robustly recover an underlying function from noisy data.

## Mathematical formulation

### The initial assumption

Suppose one wants to model the output of a computer experiment, say a mathematical function:

$$\begin{aligned} g : \mathbb{R}^{n_{\text{features}}} &\rightarrow \mathbb{R} \\ X &\mapsto y = g(X) \end{aligned}$$

GPMI starts with the assumption that this function is a conditional sample path of a Gaussian process  $G$  which is additionally assumed to read as follows:

$$G(X) = f(X)^T \beta + Z(X)$$

where  $f(X)^T \beta$  is a linear regression model and  $Z(X)$  is a zero-mean Gaussian process with a fully stationary covariance function:

$$C(X, X') = \sigma^2 R(|X - X'|)$$

$\sigma^2$  being its variance and  $R$  being the correlation function which solely depends on the absolute relative distance between each sample, possibly featurewise (this is the stationarity assumption).

From this basic formulation, note that GPMI is nothing but an extension of a basic least squares linear regression problem:

$$g(X) \approx f(X)^T \beta$$

Except we additionally assume some spatial coherence (correlation) between the samples dictated by the correlation function. Indeed, ordinary least squares assumes the correlation model  $R(|X - X'|)$  is one when  $X = X'$  and zero otherwise : a *dirac* correlation model – sometimes referred to as a *nugget* correlation model in the kriging literature.

### The best linear unbiased prediction (BLUP)

We now derive the *best linear unbiased prediction* of the sample path  $g$  conditioned on the observations:

$$\hat{G}(X) = G(X | y_1 = g(X_1), \dots, y_{n_{\text{samples}}} = g(X_{n_{\text{samples}}}))$$

It is derived from its *given properties*:

- It is linear (a linear combination of the observations)

$$\hat{G}(X) \equiv a(X)^T y$$

- It is unbiased

$$\mathbb{E}[G(X) - \hat{G}(X)] = 0$$

- It is the best (in the Mean Squared Error sense)

$$\hat{G}(X)^* = \arg \min_{\hat{G}(X)} \mathbb{E}[(G(X) - \hat{G}(X))^2]$$

So that the optimal weight vector  $a(X)$  is solution of the following equality constrained optimization problem:

$$\begin{aligned} a(X)^* &= \arg \min_{a(X)} \mathbb{E}[(G(X) - a(X)^T y)^2] \\ \text{s.t. } &\mathbb{E}[G(X) - a(X)^T y] = 0 \end{aligned}$$

Rewriting this constrained optimization problem in the form of a Lagrangian and looking further for the first order optimality conditions to be satisfied, one ends up with a closed form expression for the sought predictor – see references for the complete proof.

In the end, the BLUP is shown to be a Gaussian random variate with mean:

$$\mu_{\hat{Y}}(X) = f(X)^T \hat{\beta} + r(X)^T \gamma$$

and variance:

$$\sigma_{\hat{Y}}^2(X) = \sigma_Y^2 (1 - r(X)^T R^{-1} r(X) + u(X)^T (F^T R^{-1} F)^{-1} u(X))$$

where we have introduced:

- the correlation matrix whose terms are defined wrt the autocorrelation function and its built-in parameters  $\theta$ :

$$R_{ij} = R(|X_i - X_j|, \theta), \quad i, j = 1, \dots, m$$

- the vector of cross-correlations between the point where the prediction is made and the points in the DOE:

$$r_i = R(|X - X_i|, \theta), \quad i = 1, \dots, m$$

- the regression matrix (eg the Vandermonde matrix if  $f$  is a polynomial basis):

$$F_{ij} = f_i(X_j), \quad i = 1, \dots, p, \quad j = 1, \dots, m$$

- the generalized least square regression weights:

$$\hat{\beta} = (F^T R^{-1} F)^{-1} F^T R^{-1} Y$$

- and the vectors:

$$\gamma = R^{-1}(Y - F \hat{\beta})$$

$$u(X) = F^T R^{-1} r(X) - f(X)$$

It is important to notice that the probabilistic response of a Gaussian Process predictor is fully analytic and mostly relies on basic linear algebra operations. More precisely the mean prediction is the sum of two simple linear combinations (dot products), and the variance requires two matrix inversions, but the correlation matrix can be decomposed only once using a Cholesky decomposition algorithm.

## The empirical best linear unbiased predictor (EBLUP)

Until now, both the autocorrelation and regression models were assumed given. In practice however they are never known in advance so that one has to make (motivated) empirical choices for these models [Correlation Models](#).

Provided these choices are made, one should estimate the remaining unknown parameters involved in the BLUP. To do so, one uses the set of provided observations in conjunction with some inference technique. The present implementation, which is based on the DACE's Matlab toolbox uses the *maximum likelihood estimation* technique – see DACE manual in references for the complete equations. This maximum likelihood estimation problem is turned into a global optimization problem onto the autocorrelation parameters. In the present implementation, this global optimization is solved by means of the `fmin_cobyla` optimization function from `scipy.optimize`. In the case of anisotropy however, we provide an implementation of Welch's componentwise optimization algorithm – see references.

## Correlation Models

Common correlation models matches some famous SVM's kernels because they are mostly built on equivalent assumptions. They must fulfill Mercer's conditions and should additionally remain stationary. Note however, that the choice of the correlation model should be made in agreement with the known properties of the original experiment from which the observations come. For instance:

- If the original experiment is known to be infinitely differentiable (smooth), then one should use the *squared-exponential correlation model*.
- If it's not, then one should rather use the *exponential correlation model*.
- Note also that there exists a correlation model that takes the degree of derivability as input: this is the Matern correlation model, but it's not implemented here (TODO).

For a more detailed discussion on the selection of appropriate correlation models, see the book by Rasmussen & Williams in references.

## Regression Models

Common linear regression models involve zero- (constant), first- and second-order polynomials. But one may specify its own in the form of a Python function that takes the features X as input and that returns a vector containing the values of the functional set. The only constraint is that the number of functions must not exceed the number of available observations so that the underlying regression problem is not *underdetermined*.

### Implementation details

The implementation is based on a translation of the DACE Matlab toolbox.

### 3.1.8 Cross decomposition

The cross decomposition module contains two main families of algorithms: the partial least squares (PLS) and the canonical correlation analysis (CCA).

These families of algorithms are useful to find linear relations between two multivariate datasets: the X and Y arguments of the `fit` method are 2D arrays.

Cross decomposition algorithms find the fundamental relations between two matrices (X and Y). They are latent variable approaches to modeling the covariance structures in these two spaces. They will try to find the multidimensional direction in the X space that explains the maximum multidimensional variance direction in the Y space. PLS-regression is particularly suited when the matrix of predictors has more variables than observations, and when there is multicollinearity among X values. By contrast, standard regression will fail in these cases.

Classes included in this module are `PLSRegression` `PLSCanonical`, `CCA` and `PLSSVD`

### 3.1.9 Naive Bayes

Naive Bayes methods are a set of supervised learning algorithms based on applying Bayes' theorem with the “naive” assumption of independence between every pair of features. Given a class variable  $y$  and a dependent feature vector  $x_1$  through  $x_n$ , Bayes' theorem states the following relationship:

$$P(y | x_1, \dots, x_n) = \frac{P(y)P(x_1, \dots, x_n | y)}{P(x_1, \dots, x_n)}$$

Using the naive independence assumption that

$$P(x_i | y, x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_n) = P(x_i | y),$$

for all  $i$ , this relationship is simplified to

$$P(y | x_1, \dots, x_n) = \frac{P(y) \prod_{i=1}^n P(x_i | y)}{P(x_1, \dots, x_n)}$$

Since  $P(x_1, \dots, x_n)$  is constant given the input, we can use the following classification rule:

$$\begin{aligned} P(y | x_1, \dots, x_n) &\propto P(y) \prod_{i=1}^n P(x_i | y) \\ &\Downarrow \\ \hat{y} &= \arg \max_y P(y) \prod_{i=1}^n P(x_i | y), \end{aligned}$$

and we can use Maximum A Posteriori (MAP) estimation to estimate  $P(y)$  and  $P(x_i | y)$ ; the former is then the relative frequency of class  $y$  in the training set.

The different naive Bayes classifiers differ mainly by the assumptions they make regarding the distribution of  $P(x_i | y)$ .

In spite of their apparently over-simplified assumptions, naive Bayes classifiers have worked quite well in many real-world situations, famously document classification and spam filtering. They require a small amount of training data to estimate the necessary parameters. (For theoretical reasons why naive Bayes works well, and on which types of data it does, see the references below.)

Naive Bayes learners and classifiers can be extremely fast compared to more sophisticated methods. The decoupling of the class conditional feature distributions means that each distribution can be independently estimated as a one dimensional distribution. This in turn helps to alleviate problems stemming from the curse of dimensionality.

On the flip side, although naive Bayes is known as a decent classifier, it is known to be a bad estimator, so the probability outputs from `predict_proba` are not to be taken too seriously.

## References:

- H. Zhang (2004). The optimality of Naive Bayes. Proc. FLAIRS.

## Gaussian Naive Bayes

`GaussianNB` implements the Gaussian Naive Bayes algorithm for classification. The likelihood of the features is assumed to be Gaussian:

$$P(x_i | y) = \frac{1}{\sqrt{2\pi\sigma_y^2}} \exp\left(-\frac{(x_i - \mu_y)^2}{2\sigma_y^2}\right)$$

The parameters  $\sigma_y$  and  $\mu_y$  are estimated using maximum likelihood.

```
>>> from sklearn import datasets
>>> iris = datasets.load_iris()
>>> from sklearn.naive_bayes import GaussianNB
>>> gnb = GaussianNB()
>>> y_pred = gnb.fit(iris.data, iris.target).predict(iris.data)
>>> print("Number of mislabeled points out of a total %d points : %d"
...      % (iris.data.shape[0], (iris.target != y_pred).sum()))
Number of mislabeled points out of a total 150 points : 6
```

## Multinomial Naive Bayes

`MultinomialNB` implements the naive Bayes algorithm for multinomially distributed data, and is one of the two classic naive Bayes variants used in text classification (where the data are typically represented as word vector counts,

although tf-idf vectors are also known to work well in practice). The distribution is parametrized by vectors  $\theta_y = (\theta_{y1}, \dots, \theta_{yn})$  for each class  $y$ , where  $n$  is the number of features (in text classification, the size of the vocabulary) and  $\theta_{yi}$  is the probability  $P(x_i | y)$  of feature  $i$  appearing in a sample belonging to class  $y$ .

The parameters  $\theta_y$  is estimated by a smoothed version of maximum likelihood, i.e. relative frequency counting:

$$\hat{\theta}_{yi} = \frac{N_{yi} + \alpha}{N_y + \alpha n}$$

where  $N_{yi} = \sum_{x \in T} x_i$  is the number of times feature  $i$  appears in a sample of class  $y$  in the training set  $T$ , and  $N_y = \sum_{i=1}^{|T|} N_{yi}$  is the total count of all features for class  $y$ .

The smoothing priors  $\alpha \geq 0$  accounts for features not present in the learning samples and prevents zero probabilities in further computations. Setting  $\alpha = 1$  is called Laplace smoothing, while  $\alpha < 1$  is called Lidstone smoothing.

## Bernoulli Naive Bayes

`BernoulliNB` implements the naive Bayes training and classification algorithms for data that is distributed according to multivariate Bernoulli distributions; i.e., there may be multiple features but each one is assumed to be a binary-valued (Bernoulli, boolean) variable. Therefore, this class requires samples to be represented as binary-valued feature vectors; if handed any other kind of data, a `BernoulliNB` instance may binarize its input (depending on the `binarize` parameter).

The decision rule for Bernoulli naive Bayes is based on

$$P(x_i | y) = P(i | y)x_i + (1 - P(i | y))(1 - x_i)$$

which differs from multinomial NB's rule in that it explicitly penalizes the non-occurrence of a feature  $i$  that is an indicator for class  $y$ , where the multinomial variant would simply ignore a non-occurring feature.

In the case of text classification, word occurrence vectors (rather than word count vectors) may be used to train and use this classifier. `BernoulliNB` might perform better on some datasets, especially those with shorter documents. It is advisable to evaluate both models, if time permits.

## Out-of-core naive Bayes model fitting

Naive Bayes models can be used to tackle large scale classification problems for which the full training set might not fit in memory. To handle this case, `MultinomialNB`, `BernoulliNB`, and `GaussianNB` expose a `partial_fit` method that can be used incrementally as done with other classifiers as demonstrated in [Out-of-core classification of text documents](#). All naive Bayes classifiers support sample weighting.

Contrary to the `fit` method, the first call to `partial_fit` needs to be passed the list of all the expected class labels.

For an overview of available strategies in scikit-learn, see also the [out-of-core learning](#) documentation.

---

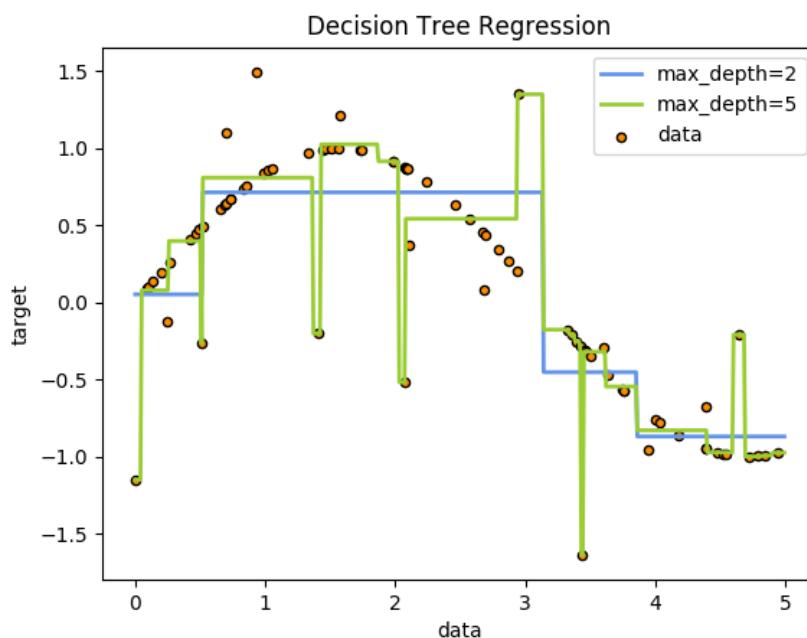

**Note:** The `partial_fit` method call of naive Bayes models introduces some computational overhead. It is recommended to use data chunk sizes that are as large as possible, that is as the available RAM allows.

---

### 3.1.10 Decision Trees

**Decision Trees (DTs)** are a non-parametric supervised learning method used for [classification](#) and [regression](#). The goal is to create a model that predicts the value of a target variable by learning simple decision rules inferred from the data features.

For instance, in the example below, decision trees learn from data to approximate a sine curve with a set of if-then-else decision rules. The deeper the tree, the more complex the decision rules and the fitter the model.

Some advantages of decision trees are:

- Simple to understand and to interpret. Trees can be visualised.
- Requires little data preparation. Other techniques often require data normalisation, dummy variables need to be created and blank values to be removed. Note however that this module does not support missing values.
- The cost of using the tree (i.e., predicting data) is logarithmic in the number of data points used to train the tree.
- Able to handle both numerical and categorical data. Other techniques are usually specialised in analysing datasets that have only one type of variable. See [algorithms](#) for more information.
- Able to handle multi-output problems.
- Uses a white box model. If a given situation is observable in a model, the explanation for the condition is easily explained by boolean logic. By contrast, in a black box model (e.g., in an artificial neural network), results may be more difficult to interpret.
- Possible to validate a model using statistical tests. That makes it possible to account for the reliability of the model.

- Performs well even if its assumptions are somewhat violated by the true model from which the data were generated.

The disadvantages of decision trees include:

- Decision-tree learners can create over-complex trees that do not generalise the data well. This is called overfitting. Mechanisms such as pruning (not currently supported), setting the minimum number of samples required at a leaf node or setting the maximum depth of the tree are necessary to avoid this problem.
- Decision trees can be unstable because small variations in the data might result in a completely different tree being generated. This problem is mitigated by using decision trees within an ensemble.
- The problem of learning an optimal decision tree is known to be NP-complete under several aspects of optimality and even for simple concepts. Consequently, practical decision-tree learning algorithms are based on heuristic algorithms such as the greedy algorithm where locally optimal decisions are made at each node. Such algorithms cannot guarantee to return the globally optimal decision tree. This can be mitigated by training multiple trees in an ensemble learner, where the features and samples are randomly sampled with replacement.
- There are concepts that are hard to learn because decision trees do not express them easily, such as XOR, parity or multiplexer problems.
- Decision tree learners create biased trees if some classes dominate. It is therefore recommended to balance the dataset prior to fitting with the decision tree.

## Classification

*DecisionTreeClassifier* is a class capable of performing multi-class classification on a dataset.

As with other classifiers, *DecisionTreeClassifier* takes as input two arrays: an array X, sparse or dense, of size [n\_samples, n\_features] holding the training samples, and an array Y of integer values, size [n\_samples], holding the class labels for the training samples:

```
>>> from sklearn import tree
>>> X = [[0, 0], [1, 1]]
>>> Y = [0, 1]
>>> clf = tree.DecisionTreeClassifier()
>>> clf = clf.fit(X, Y)
```

After being fitted, the model can then be used to predict the class of samples:

```
>>> clf.predict([[2., 2.]])
array([1])
```

Alternatively, the probability of each class can be predicted, which is the fraction of training samples of the same class in a leaf:

```
>>> clf.predict_proba([[2., 2.]])
array([[ 0.,  1.]])
```

*DecisionTreeClassifier* is capable of both binary (where the labels are [-1, 1]) classification and multiclass (where the labels are [0, ..., K-1]) classification.

Using the Iris dataset, we can construct a tree as follows:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn import tree
>>> iris = load_iris()
>>> clf = tree.DecisionTreeClassifier()
>>> clf = clf.fit(iris.data, iris.target)
```

Once trained, we can export the tree in `Graphviz` format using the `export_graphviz` exporter. Below is an example export of a tree trained on the entire iris dataset:

```
>>> with open("iris.dot", 'w') as f:  
...     f = tree.export_graphviz(clf, out_file=f)
```

Then we can use Graphviz's dot tool to create a PDF file (or any other supported file type): `dot -Tpdf iris.dot -o iris.pdf`.

```
>>> import os  
>>> os.unlink('iris.dot')
```

Alternatively, if we have Python module `pydotplus` installed, we can generate a PDF file (or any other supported file type) directly in Python:

```
>>> import pydotplus  
>>> dot_data = tree.export_graphviz(clf, out_file=None)  
>>> graph = pydotplus.graph_from_dot_data(dot_data)  
>>> graph.write_pdf("iris.pdf")
```

The `export_graphviz` exporter also supports a variety of aesthetic options, including coloring nodes by their class (or value for regression) and using explicit variable and class names if desired. IPython notebooks can also render these plots inline using the `Image()` function:

```
>>> from IPython.display import Image  
>>> dot_data = tree.export_graphviz(clf, out_file=None,  
...                                 feature_names=iris.feature_names,  
...                                 class_names=iris.target_names,  
...                                 filled=True, rounded=True,  
...                                 special_characters=True)  
>>> graph = pydotplus.graph_from_dot_data(dot_data)  
>>> Image(graph.create_png())
```

After being fitted, the model can then be used to predict the class of samples:

```
>>> clf.predict(iris.data[:1, :])  
array([0])
```

Alternatively, the probability of each class can be predicted, which is the fraction of training samples of the same class in a leaf:

```
>>> clf.predict_proba(iris.data[:1, :])  
array([[ 1.,  0.,  0.]])
```

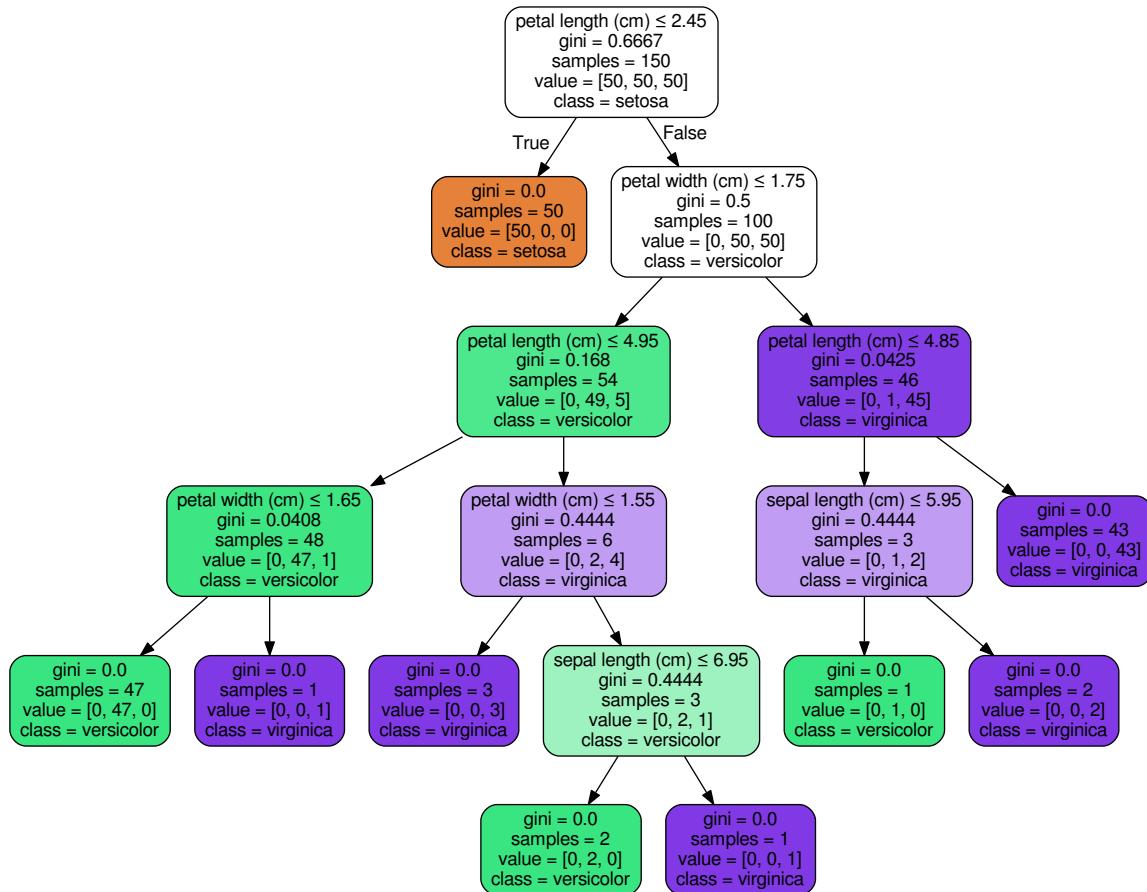

## Examples:

- *Plot the decision surface of a decision tree on the iris dataset*

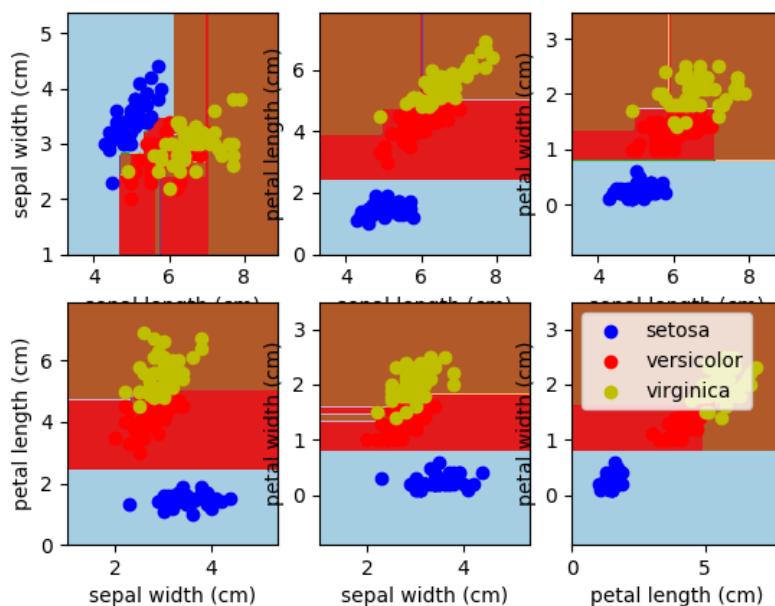

## Regression

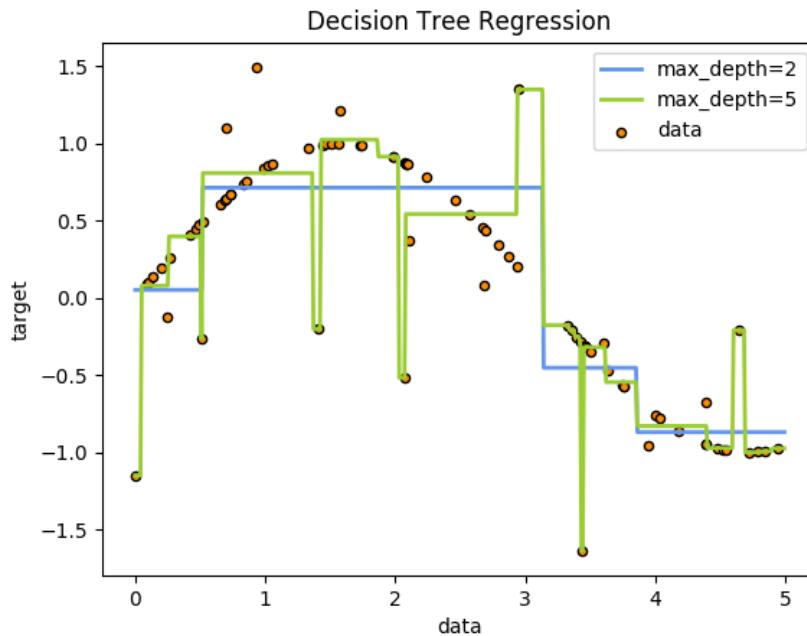

Decision trees can also be applied to regression problems, using the `DecisionTreeRegressor` class.

As in the classification setting, the `fit` method will take as argument arrays `X` and `y`, only that in this case `y` is expected to have floating point values instead of integer values:

Decision surface of a decision tree using paired features

```
>>> from sklearn import tree
>>> X = [[0, 0], [2, 2]]
>>> y = [0.5, 2.5]
>>> clf = tree.DecisionTreeRegressor()
>>> clf = clf.fit(X, y)
>>> clf.predict([[1, 1]])
array([ 0.5])
```

### Examples:

- *Decision Tree Regression*

## Multi-output problems

A multi-output problem is a supervised learning problem with several outputs to predict, that is when  $Y$  is a 2d array of size  $[n\_samples, n\_outputs]$ .

When there is no correlation between the outputs, a very simple way to solve this kind of problem is to build  $n$  independent models, i.e. one for each output, and then to use those models to independently predict each one of the  $n$  outputs. However, because it is likely that the output values related to the same input are themselves correlated, an often better way is to build a single model capable of predicting simultaneously all  $n$  outputs. First, it requires lower training time since only a single estimator is built. Second, the generalization accuracy of the resulting estimator may often be increased.

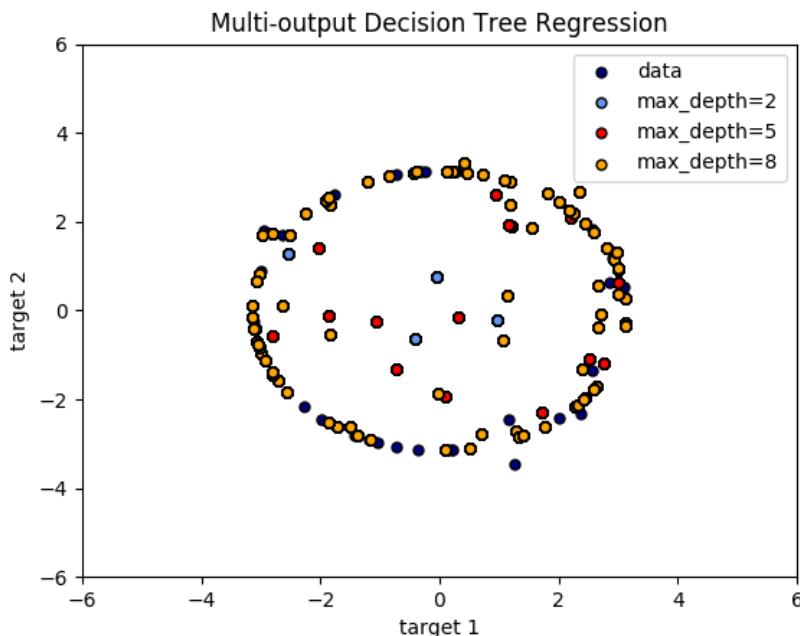

With regard to decision trees, this strategy can readily be used to support multi-output problems. This requires the following changes:

- Store  $n$  output values in leaves, instead of 1;
- Use splitting criteria that compute the average reduction across all  $n$  outputs.

This module offers support for multi-output problems by implementing this strategy in both `DecisionTreeClassifier` and `DecisionTreeRegressor`. If a decision tree is fit on an output array Y of size [n\_samples, n\_outputs] then the resulting estimator will:

- Output n\_output values upon `predict`;
- Output a list of n\_output arrays of class probabilities upon `predict_proba`.

The use of multi-output trees for regression is demonstrated in [Multi-output Decision Tree Regression](#). In this example, the input X is a single real value and the outputs Y are the sine and cosine of X.

The use of multi-output trees for classification is demonstrated in [Face completion with a multi-output estimators](#). In this example, the inputs X are the pixels of the upper half of faces and the outputs Y are the pixels of the lower half of those faces.

### Face completion with multi-output estimators

## Complexity

In general, the run time cost to construct a balanced binary tree is  $O(n_{samples}n_{features} \log(n_{samples}))$  and query time  $O(\log(n_{samples}))$ . Although the tree construction algorithm attempts to generate balanced trees, they will not always be balanced. Assuming that the subtrees remain approximately balanced, the cost at each node consists of searching through  $O(n_{features})$  to find the feature that offers the largest reduction in entropy. This has a cost of  $O(n_{features}n_{samples} \log(n_{samples}))$  at each node, leading to a total cost over the entire trees (by summing the cost at each node) of  $O(n_{features}n_{samples}^2 \log(n_{samples}))$ .

Scikit-learn offers a more efficient implementation for the construction of decision trees. A naive implementation (as above) would recompute the class label histograms (for classification) or the means (for regression) at for each new split point along a given feature. Presorting the feature over all relevant samples, and retaining a running label count, will reduce the complexity at each node to  $O(n_{features} \log(n_{samples}))$ , which results in a total cost of  $O(n_{features}n_{samples} \log(n_{samples}))$ . This is an option for all tree based algorithms. By default it is turned on for gradient boosting, where in general it makes training faster, but turned off for all other algorithms as it tends to slow down training when training deep trees.

## Tips on practical use

- Decision trees tend to overfit on data with a large number of features. Getting the right ratio of samples to number of features is important, since a tree with few samples in high dimensional space is very likely to overfit.
- Consider performing dimensionality reduction ([PCA](#), [ICA](#), or [Feature selection](#)) beforehand to give your tree a better chance of finding features that are discriminative.
- Visualise your tree as you are training by using the `export` function. Use `max_depth=3` as an initial tree depth to get a feel for how the tree is fitting to your data, and then increase the depth.
- Remember that the number of samples required to populate the tree doubles for each additional level the tree grows to. Use `max_depth` to control the size of the tree to prevent overfitting.
- Use `min_samples_split` or `min_samples_leaf` to control the number of samples at a leaf node. A very small number will usually mean the tree will overfit, whereas a large number will prevent the tree from learning the data. Try `min_samples_leaf=5` as an initial value. If the sample size varies greatly, a float number can be used as percentage in these two parameters. The main difference between the two is that `min_samples_leaf` guarantees a minimum number of samples in a leaf, while `min_samples_split` can create arbitrary small leaves, though `min_samples_split` is more common in the literature.
- Balance your dataset before training to prevent the tree from being biased toward the classes that are dominant. Class balancing can be done by sampling an equal number of samples from each class, or preferably by normalizing the sum of the sample weights (`sample_weight`) for each class to the same value. Also note that weight-based pre-pruning criteria, such as `min_weight_fraction_leaf`, will then be less biased toward dominant classes than criteria that are not aware of the sample weights, like `min_samples_leaf`.
- If the samples are weighted, it will be easier to optimize the tree structure using weight-based pre-pruning criterion such as `min_weight_fraction_leaf`, which ensure that leaf nodes contain at least a fraction of the overall sum of the sample weights.
- All decision trees use `np.float32` arrays internally. If training data is not in this format, a copy of the dataset will be made.
- If the input matrix `X` is very sparse, it is recommended to convert to sparse `csc_matrix` before calling `fit` and sparse `csr_matrix` before calling `predict`. Training time can be orders of magnitude faster for a sparse matrix input compared to a dense matrix when features have zero values in most of the samples.

## Tree algorithms: ID3, C4.5, C5.0 and CART

What are all the various decision tree algorithms and how do they differ from each other? Which one is implemented in scikit-learn?

**ID3** (Iterative Dichotomiser 3) was developed in 1986 by Ross Quinlan. The algorithm creates a multiway tree, finding for each node (i.e. in a greedy manner) the categorical feature that will yield the largest information gain for categorical targets. Trees are grown to their maximum size and then a pruning step is usually applied to improve the ability of the tree to generalise to unseen data.

C4.5 is the successor to ID3 and removed the restriction that features must be categorical by dynamically defining a discrete attribute (based on numerical variables) that partitions the continuous attribute value into a discrete set of intervals. C4.5 converts the trained trees (i.e. the output of the ID3 algorithm) into sets of if-then rules. These accuracy of each rule is then evaluated to determine the order in which they should be applied. Pruning is done by removing a rule's precondition if the accuracy of the rule improves without it.

C5.0 is Quinlan's latest version release under a proprietary license. It uses less memory and builds smaller rulesets than C4.5 while being more accurate.

**CART** (Classification and Regression Trees) is very similar to C4.5, but it differs in that it supports numerical target variables (regression) and does not compute rule sets. CART constructs binary trees using the feature and threshold that yield the largest information gain at each node.

scikit-learn uses an optimised version of the CART algorithm.

## Mathematical formulation

Given training vectors  $x_i \in R^n$ ,  $i=1, \dots, l$  and a label vector  $y \in R^l$ , a decision tree recursively partitions the space such that the samples with the same labels are grouped together.

Let the data at node  $m$  be represented by  $Q$ . For each candidate split  $\theta = (j, t_m)$  consisting of a feature  $j$  and threshold  $t_m$ , partition the data into  $Q_{left}(\theta)$  and  $Q_{right}(\theta)$  subsets

$$\begin{aligned} Q_{left}(\theta) &= (x, y) | x_j \leq t_m \\ Q_{right}(\theta) &= Q \setminus Q_{left}(\theta) \end{aligned}$$

The impurity at  $m$  is computed using an impurity function  $H()$ , the choice of which depends on the task being solved (classification or regression)

$$G(Q, \theta) = \frac{n_{left}}{N_m} H(Q_{left}(\theta)) + \frac{n_{right}}{N_m} H(Q_{right}(\theta))$$

Select the parameters that minimises the impurity

$$\theta^* = \operatorname{argmin}_{\theta} G(Q, \theta)$$

Recurse for subsets  $Q_{left}(\theta^*)$  and  $Q_{right}(\theta^*)$  until the maximum allowable depth is reached,  $N_m < \text{min}_samples$  or  $N_m = 1$ .

## Classification criteria

If a target is a classification outcome taking on values 0,1,...,K-1, for node  $m$ , representing a region  $R_m$  with  $N_m$  observations, let

$$p_{mk} = 1/N_m \sum_{x_i \in R_m} I(y_i = k)$$

be the proportion of class  $k$  observations in node  $m$

Common measures of impurity are Gini

$$H(X_m) = \sum_k p_{mk}(1 - p_{mk})$$

Cross-Entropy

$$H(X_m) = - \sum_k p_{mk} \log(p_{mk})$$

and Misclassification

$$H(X_m) = 1 - \max(p_{mk})$$

where  $X_m$  is the training data in node  $m$

## Regression criteria

If the target is a continuous value, then for node  $m$ , representing a region  $R_m$  with  $N_m$  observations, common criteria to minimise are

Mean Squared Error:

$$\begin{aligned} c_m &= \frac{1}{N_m} \sum_{i \in N_m} y_i \\ H(X_m) &= \frac{1}{N_m} \sum_{i \in N_m} (y_i - c_m)^2 \end{aligned}$$

Mean Absolute Error:

$$\begin{aligned} \bar{y}_m &= \frac{1}{N_m} \sum_{i \in N_m} y_i \\ H(X_m) &= \frac{1}{N_m} \sum_{i \in N_m} |y_i - \bar{y}_m| \end{aligned}$$

where  $X_m$  is the training data in node  $m$

### 3.1.11 Ensemble methods

The goal of **ensemble methods** is to combine the predictions of several base estimators built with a given learning algorithm in order to improve generalizability / robustness over a single estimator.

Two families of ensemble methods are usually distinguished:

- In **averaging methods**, the driving principle is to build several estimators independently and then to average their predictions. On average, the combined estimator is usually better than any of the single base estimator because its variance is reduced.

**Examples:** *Bagging methods, Forests of randomized trees, ...*

- By contrast, in **boosting methods**, base estimators are built sequentially and one tries to reduce the bias of the combined estimator. The motivation is to combine several weak models to produce a powerful ensemble.

**Examples:** *AdaBoost, Gradient Tree Boosting, ...*

## Bagging meta-estimator

In ensemble algorithms, bagging methods form a class of algorithms which build several instances of a black-box estimator on random subsets of the original training set and then aggregate their individual predictions to form a final prediction. These methods are used as a way to reduce the variance of a base estimator (e.g., a decision tree), by introducing randomization into its construction procedure and then making an ensemble out of it. In many cases, bagging methods constitute a very simple way to improve with respect to a single model, without making it necessary to adapt the underlying base algorithm. As they provide a way to reduce overfitting, bagging methods work best with strong and complex models (e.g., fully developed decision trees), in contrast with boosting methods which usually work best with weak models (e.g., shallow decision trees).

Bagging methods come in many flavours but mostly differ from each other by the way they draw random subsets of the training set:

- When random subsets of the dataset are drawn as random subsets of the samples, then this algorithm is known as Pasting [[B1999](#)].
- When samples are drawn with replacement, then the method is known as Bagging [[B1996](#)].
- When random subsets of the dataset are drawn as random subsets of the features, then the method is known as Random Subspaces [[H1998](#)].
- Finally, when base estimators are built on subsets of both samples and features, then the method is known as Random Patches [[LG2012](#)].

In scikit-learn, bagging methods are offered as a unified `BaggingClassifier` meta-estimator (resp. `BaggingRegressor`), taking as input a user-specified base estimator along with parameters specifying the strategy to draw random subsets. In particular, `max_samples` and `max_features` control the size of the subsets (in terms of samples and features), while `bootstrap` and `bootstrap_features` control whether samples and features are drawn with or without replacement. When using a subset of the available samples the generalization accuracy can be estimated with the out-of-bag samples by setting `oob_score=True`. As an example, the snippet below illustrates how to instantiate a bagging ensemble of `KNeighborsClassifier` base estimators, each built on random subsets of 50% of the samples and 50% of the features.

```
>>> from sklearn.ensemble import BaggingClassifier
>>> from sklearn.neighbors import KNeighborsClassifier
>>> bagging = BaggingClassifier(KNeighborsClassifier(),
...                             max_samples=0.5, max_features=0.5)
```

## References

### Forests of randomized trees

The `sklearn.ensemble` module includes two averaging algorithms based on randomized *decision trees*: the RandomForest algorithm and the Extra-Trees method. Both algorithms are perturb-and-combine techniques [B1998] specifically designed for trees. This means a diverse set of classifiers is created by introducing randomness in the classifier construction. The prediction of the ensemble is given as the averaged prediction of the individual classifiers.

As other classifiers, forest classifiers have to be fitted with two arrays: a sparse or dense array X of size [`n_samples`, `n_features`] holding the training samples, and an array Y of size [`n_samples`] holding the target values (class labels) for the training samples:

```
>>> from sklearn.ensemble import RandomForestClassifier
>>> X = [[0, 0], [1, 1]]
>>> Y = [0, 1]
>>> clf = RandomForestClassifier(n_estimators=10)
>>> clf = clf.fit(X, Y)
```

Like *decision trees*, forests of trees also extend to *multi-output problems* (if Y is an array of size [`n_samples`, `n_outputs`]).

### Random Forests

In random forests (see `RandomForestClassifier` and `RandomForestRegressor` classes), each tree in the ensemble is built from a sample drawn with replacement (i.e., a bootstrap sample) from the training set. In addition, when splitting a node during the construction of the tree, the split that is chosen is no longer the best split among all features. Instead, the split that is picked is the best split among a random subset of the features. As a result of this randomness, the bias of the forest usually slightly increases (with respect to the bias of a single non-random tree) but, due to averaging, its variance also decreases, usually more than compensating for the increase in bias, hence yielding an overall better model.

In contrast to the original publication [B2001], the scikit-learn implementation combines classifiers by averaging their probabilistic prediction, instead of letting each classifier vote for a single class.

### Extremely Randomized Trees

In extremely randomized trees (see `ExtraTreesClassifier` and `ExtraTreesRegressor` classes), randomness goes one step further in the way splits are computed. As in random forests, a random subset of candidate features is used, but instead of looking for the most discriminative thresholds, thresholds are drawn at random for each candidate feature and the best of these randomly-generated thresholds is picked as the splitting rule. This usually allows to reduce the variance of the model a bit more, at the expense of a slightly greater increase in bias:

```
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.datasets import make_blobs
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.ensemble import ExtraTreesClassifier
>>> from sklearn.tree import DecisionTreeClassifier

>>> X, y = make_blobs(n_samples=10000, n_features=10,
...                     random_state=0)
```

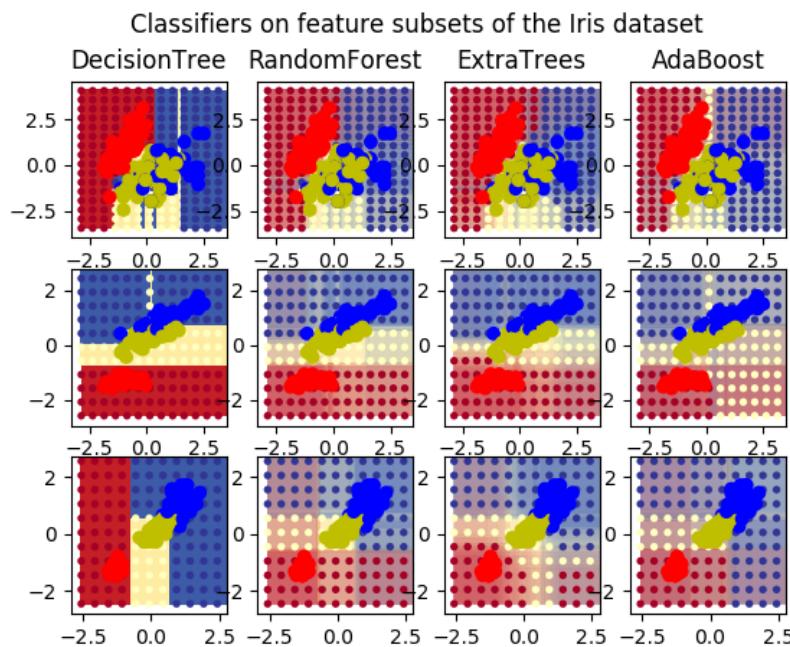

```

>>> clf = DecisionTreeClassifier(max_depth=None, min_samples_split=2,
...     random_state=0)
>>> scores = cross_val_score(clf, X, y)
>>> scores.mean()
0.97...

>>> clf = RandomForestClassifier(n_estimators=10, max_depth=None,
...     min_samples_split=2, random_state=0)
>>> scores = cross_val_score(clf, X, y)
>>> scores.mean()
0.999...

>>> clf = ExtraTreesClassifier(n_estimators=10, max_depth=None,
...     min_samples_split=2, random_state=0)
>>> scores = cross_val_score(clf, X, y)
>>> scores.mean() > 0.999
True

```

## Parameters

The main parameters to adjust when using these methods is `n_estimators` and `max_features`. The former is the number of trees in the forest. The larger the better, but also the longer it will take to compute. In addition, note that results will stop getting significantly better beyond a critical number of trees. The latter is the size of the random subsets of features to consider when splitting a node. The lower the greater the reduction of variance, but also the greater the increase in bias. Empirical good default values are `max_features=n_features` for regression problems, and `max_features=sqrt(n_features)` for classification tasks (where `n_features` is the number of features in the data). Good results are often achieved when setting `max_depth=None` in combination with `min_samples_split=1` (i.e., when fully developing the trees). Bear in mind though that these values are usually not optimal, and might result in models that consume a lot of RAM. The best parameter values should always be cross-validated. In addition, note that in random forests, bootstrap samples are used by default (`bootstrap=True`)

while the default strategy for extra-trees is to use the whole dataset (`bootstrap=False`). When using bootstrap sampling the generalization accuracy can be estimated on the left out or out-of-bag samples. This can be enabled by setting `oob_score=True`.

---

**Note:** The size of the model with the default parameters is  $O(M * N * \log(N))$ , where  $M$  is the number of trees and  $N$  is the number of samples. In order to reduce the size of the model, you can change these parameters: `min_samples_split`, `min_samples_leaf`, `max_leaf_nodes` and `max_depth`.

---

## Parallelization

Finally, this module also features the parallel construction of the trees and the parallel computation of the predictions through the `n_jobs` parameter. If `n_jobs=k` then computations are partitioned into  $k$  jobs, and run on  $k$  cores of the machine. If `n_jobs=-1` then all cores available on the machine are used. Note that because of inter-process communication overhead, the speedup might not be linear (i.e., using  $k$  jobs will unfortunately not be  $k$  times as fast). Significant speedup can still be achieved though when building a large number of trees, or when building a single tree requires a fair amount of time (e.g., on large datasets).

### Examples:

- *Plot the decision surfaces of ensembles of trees on the iris dataset*
- *Pixel importances with a parallel forest of trees*
- *Face completion with a multi-output estimators*

### References

## Feature importance evaluation

The relative rank (i.e. depth) of a feature used as a decision node in a tree can be used to assess the relative importance of that feature with respect to the predictability of the target variable. Features used at the top of the tree contribute to the final prediction decision of a larger fraction of the input samples. The **expected fraction of the samples** they contribute to can thus be used as an estimate of the **relative importance of the features**.

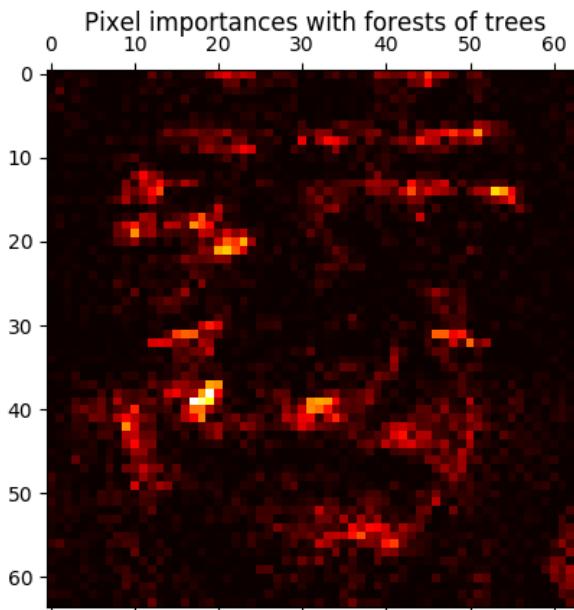

By **averaging** those expected activity rates over several randomized trees one can **reduce the variance** of such an estimate and use it for feature selection.

The following example shows a color-coded representation of the relative importances of each individual pixel for a face recognition task using a `ExtraTreesClassifier` model.

In practice those estimates are stored as an attribute named `feature_importances_` on the fitted model. This is an array with shape `(n_features, )` whose values are positive and sum to 1.0. The higher the value, the more important is the contribution of the matching feature to the prediction function.

### Examples:

- *Pixel importances with a parallel forest of trees*
- *Feature importances with forests of trees*

## Totally Random Trees Embedding

`RandomTreesEmbedding` implements an unsupervised transformation of the data. Using a forest of completely random trees, `RandomTreesEmbedding` encodes the data by the indices of the leaves a data point ends up in. This index is then encoded in a one-of-K manner, leading to a high dimensional, sparse binary coding. This coding can be computed very efficiently and can then be used as a basis for other learning tasks. The size and sparsity of the code can be influenced by choosing the number of trees and the maximum depth per tree. For each tree in the ensemble, the coding contains one entry of one. The size of the coding is at most `n_estimators * 2 ** max_depth`, the maximum number of leaves in the forest.

As neighboring data points are more likely to lie within the same leaf of a tree, the transformation performs an implicit, non-parametric density estimation.

### Examples:

- *Hashing feature transformation using Totally Random Trees*
- *Manifold learning on handwritten digits: Locally Linear Embedding, Isomap...* compares non-linear dimensionality reduction techniques on handwritten digits.
- *Feature transformations with ensembles of trees* compares supervised and unsupervised tree based feature transformations.

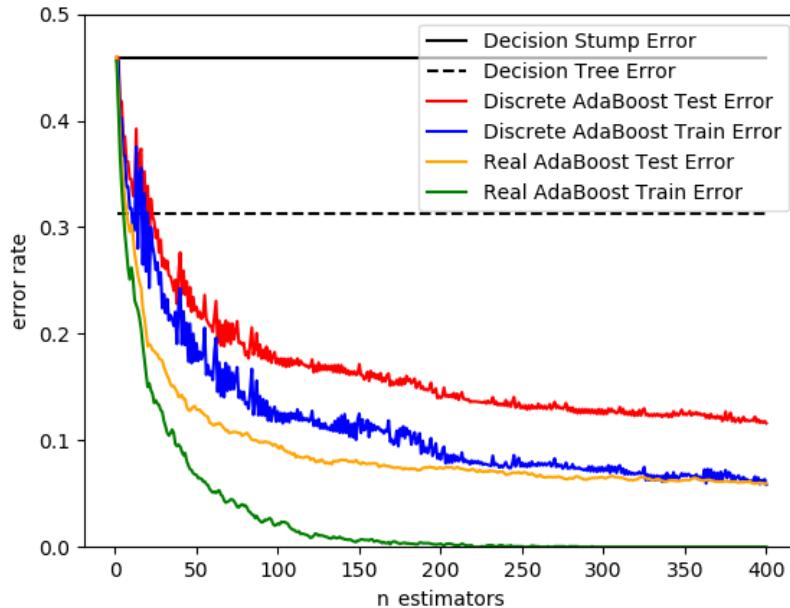

### See also:

*Manifold learning* techniques can also be useful to derive non-linear representations of feature space, also these approaches focus also on dimensionality reduction.

## AdaBoost

The module `sklearn.ensemble` includes the popular boosting algorithm AdaBoost, introduced in 1995 by Freund and Schapire [FS1995].

The core principle of AdaBoost is to fit a sequence of weak learners (i.e., models that are only slightly better than random guessing, such as small decision trees) on repeatedly modified versions of the data. The predictions from all of them are then combined through a weighted majority vote (or sum) to produce the final prediction. The data modifications at each so-called boosting iteration consist of applying weights  $w_1, w_2, \dots, w_N$  to each of the training samples. Initially, those weights are all set to  $w_i = 1/N$ , so that the first step simply trains a weak learner on the original data. For each successive iteration, the sample weights are individually modified and the learning algorithm is reapplied to the reweighted data. At a given step, those training examples that were incorrectly predicted by the boosted model induced at the previous step have their weights increased, whereas the weights are decreased for those that were predicted correctly. As iterations proceed, examples that are difficult to predict receive ever-increasing influence. Each subsequent weak learner is thereby forced to concentrate on the examples that are missed by the previous ones in the sequence [HTF].

AdaBoost can be used both for classification and regression problems:

- For multi-class classification, `AdaBoostClassifier` implements AdaBoost-SAMME and AdaBoost-SAMME.R [ZZRH2009].
- For regression, `AdaBoostRegressor` implements AdaBoost.R2 [D1997].

## Usage

The following example shows how to fit an AdaBoost classifier with 100 weak learners:

```
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.datasets import load_iris
>>> from sklearn.ensemble import AdaBoostClassifier
```

```
>>> iris = load_iris()
>>> clf = AdaBoostClassifier(n_estimators=100)
>>> scores = cross_val_score(clf, iris.data, iris.target)
>>> scores.mean()
0.9...
```

The number of weak learners is controlled by the parameter `n_estimators`. The `learning_rate` parameter controls the contribution of the weak learners in the final combination. By default, weak learners are decision stumps. Different weak learners can be specified through the `base_estimator` parameter. The main parameters to tune to obtain good results are `n_estimators` and the complexity of the base estimators (e.g., its depth `max_depth` or minimum required number of samples at a leaf `min_samples_leaf` in case of decision trees).

### Examples:

- [\*Discrete versus Real AdaBoost\*](#) compares the classification error of a decision stump, decision tree, and a boosted decision stump using AdaBoost-SAMME and AdaBoost-SAMME.R.
- [\*Multi-class AdaBoosted Decision Trees\*](#) shows the performance of AdaBoost-SAMME and AdaBoost-SAMME.R on a multi-class problem.
- [\*Two-class AdaBoost\*](#) shows the decision boundary and decision function values for a non-linearly separable two-class problem using AdaBoost-SAMME.
- [\*Decision Tree Regression with AdaBoost\*](#) demonstrates regression with the AdaBoost.R2 algorithm.

## Gradient Tree Boosting

Gradient Tree Boosting or Gradient Boosted Regression Trees (GBRT) is a generalization of boosting to arbitrary differentiable loss functions. GBRT is an accurate and effective off-the-shelf procedure that can be used for both regression and classification problems. Gradient Tree Boosting models are used in a variety of areas including Web search ranking and ecology.

The advantages of GBRT are:

- Natural handling of data of mixed type (= heterogeneous features)
- Predictive power
- Robustness to outliers in output space (via robust loss functions)

The disadvantages of GBRT are:

- Scalability, due to the sequential nature of boosting it can hardly be parallelized.

The module `sklearn.ensemble` provides methods for both classification and regression via gradient boosted regression trees.

## Classification

`GradientBoostingClassifier` supports both binary and multi-class classification. The following example shows how to fit a gradient boosting classifier with 100 decision stumps as weak learners:

```
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier

>>> X, y = make_hastie_10_2(random_state=0)
>>> X_train, X_test = X[:2000], X[2000:]
>>> y_train, y_test = y[:2000], y[2000:]

>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
...     max_depth=1, random_state=0).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.913...
```

The number of weak learners (i.e. regression trees) is controlled by the parameter `n_estimators`; *The size of each tree* can be controlled either by setting the tree depth via `max_depth` or by setting the number of leaf nodes via `max_leaf_nodes`. The `learning_rate` is a hyper-parameter in the range (0.0, 1.0] that controls overfitting via `shrinkage`.

---

**Note:** Classification with more than 2 classes requires the induction of `n_classes` regression trees at each iteration, thus, the total number of induced trees equals `n_classes * n_estimators`. For datasets with a large number of classes we strongly recommend to use `RandomForestClassifier` as an alternative to `GradientBoostingClassifier`.

---

## Regression

`GradientBoostingRegressor` supports a number of *different loss functions* for regression which can be specified via the argument `loss`; the default loss function for regression is least squares ('ls').

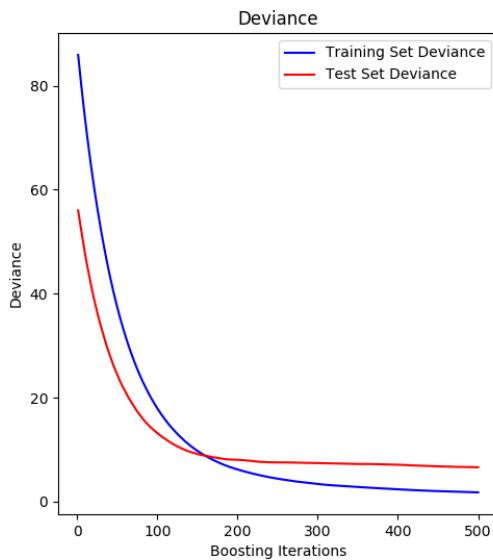

```
>>> import numpy as np
>>> from sklearn.metrics import mean_squared_error
>>> from sklearn.datasets import make_friedman1
>>> from sklearn.ensemble import GradientBoostingRegressor

>>> X, y = make_friedman1(n_samples=1200, random_state=0, noise=1.0)
>>> X_train, X_test = X[:200], X[200:]
>>> y_train, y_test = y[:200], y[200:]
>>> est = GradientBoostingRegressor(n_estimators=100, learning_rate=0.1,
...     max_depth=1, random_state=0, loss='ls').fit(X_train, y_train)
>>> mean_squared_error(y_test, est.predict(X_test))
5.00...
```

The figure below shows the results of applying `GradientBoostingRegressor` with least squares loss and 500 base learners to the Boston house price dataset (`sklearn.datasets.load_boston`). The plot on the left shows the train and test error at each iteration. The train error at each iteration is stored in the `train_score_` attribute of the gradient boosting model. The test error at each iterations can be obtained via the `staged_predict` method which returns a generator that yields the predictions at each stage. Plots like these can be used to determine the optimal number of trees (i.e. `n_estimators`) by early stopping. The plot on the right shows the feature importances which can be obtained via the `feature_importances_` property.

### Examples:

- *Gradient Boosting regression*

- Gradient Boosting Out-of-Bag estimates

## Fitting additional weak-learners

Both `GradientBoostingRegressor` and `GradientBoostingClassifier` support `warm_start=True` which allows you to add more estimators to an already fitted model.

```
>>> _ = est.set_params(n_estimators=200, warm_start=True) # set warm_start and new_
   ↵nr of trees
>>> _ = est.fit(X_train, y_train) # fit additional 100 trees to est
>>> mean_squared_error(y_test, est.predict(X_test))
3.84...
```

## Controlling the tree size

The size of the regression tree base learners defines the level of variable interactions that can be captured by the gradient boosting model. In general, a tree of depth  $h$  can capture interactions of order  $h$ . There are two ways in which the size of the individual regression trees can be controlled.

If you specify `max_depth=h` then complete binary trees of depth  $h$  will be grown. Such trees will have (at most)  $2^{*}h$  leaf nodes and  $2^{*}h - 1$  split nodes.

Alternatively, you can control the tree size by specifying the number of leaf nodes via the parameter `max_leaf_nodes`. In this case, trees will be grown using best-first search where nodes with the highest improvement in impurity will be expanded first. A tree with `max_leaf_nodes=k` has  $k - 1$  split nodes and thus can model interactions of up to order `max_leaf_nodes - 1`.

We found that `max_leaf_nodes=k` gives comparable results to `max_depth=k-1` but is significantly faster to train at the expense of a slightly higher training error. The parameter `max_leaf_nodes` corresponds to the variable  $J$  in the chapter on gradient boosting in [F2001] and is related to the parameter `interaction.depth` in R's gbm package where `max_leaf_nodes == interaction.depth + 1`.

## Mathematical formulation

GBRT considers additive models of the following form:

$$F(x) = \sum_{m=1}^M \gamma_m h_m(x)$$

where  $h_m(x)$  are the basis functions which are usually called *weak learners* in the context of boosting. Gradient Tree Boosting uses *decision trees* of fixed size as weak learners. Decision trees have a number of abilities that make them valuable for boosting, namely the ability to handle data of mixed type and the ability to model complex functions.

Similar to other boosting algorithms GBRT builds the additive model in a forward stagewise fashion:

$$F_m(x) = F_{m-1}(x) + \gamma_m h_m(x)$$

At each stage the decision tree  $h_m(x)$  is chosen to minimize the loss function  $L$  given the current model  $F_{m-1}$  and its fit  $F_{m-1}(x_i)$

$$F_m(x) = F_{m-1}(x) + \arg \min_h \sum_{i=1}^n L(y_i, F_{m-1}(x_i) - h(x))$$

The initial model  $F_0$  is problem specific, for least-squares regression one usually chooses the mean of the target values.

---

**Note:** The initial model can also be specified via the `init` argument. The passed object has to implement `fit` and `predict`.

---

Gradient Boosting attempts to solve this minimization problem numerically via steepest descent: The steepest descent direction is the negative gradient of the loss function evaluated at the current model  $F_{m-1}$  which can be calculated for any differentiable loss function:

$$F_m(x) = F_{m-1}(x) + \gamma_m \sum_{i=1}^n \nabla_F L(y_i, F_{m-1}(x_i))$$

Where the step length  $\gamma_m$  is chosen using line search:

$$\gamma_m = \arg \min_\gamma \sum_{i=1}^n L(y_i, F_{m-1}(x_i) - \gamma \frac{\partial L(y_i, F_{m-1}(x_i))}{\partial F_{m-1}(x_i)})$$

The algorithms for regression and classification only differ in the concrete loss function used.

## Loss Functions

The following loss functions are supported and can be specified using the parameter `loss`:

- Regression
  - Least squares ('ls'): The natural choice for regression due to its superior computational properties. The initial model is given by the mean of the target values.
  - Least absolute deviation ('lad'): A robust loss function for regression. The initial model is given by the median of the target values.
  - Huber ('huber'): Another robust loss function that combines least squares and least absolute deviation; use `alpha` to control the sensitivity with regards to outliers (see [\[F2001\]](#) for more details).
  - Quantile ('quantile'): A loss function for quantile regression. Use  $0 < \text{alpha} < 1$  to specify the quantile. This loss function can be used to create prediction intervals (see [Prediction Intervals for Gradient Boosting Regression](#)).
- Classification
  - Binomial deviance ('deviance'): The negative binomial log-likelihood loss function for binary classification (provides probability estimates). The initial model is given by the log odds-ratio.
  - Multinomial deviance ('deviance'): The negative multinomial log-likelihood loss function for multi-class classification with `n_classes` mutually exclusive classes. It provides probability estimates. The initial model is given by the prior probability of each class. At each iteration `n_classes` regression trees have to be constructed which makes GBRT rather inefficient for data sets with a large number of classes.
  - Exponential loss ('exponential'): The same loss function as [AdaBoostClassifier](#). Less robust to mislabeled examples than 'deviance'; can only be used for binary classification.

## Regularization

### Shrinkage

[\[F2001\]](#) proposed a simple regularization strategy that scales the contribution of each weak learner by a factor  $\nu$ :

$$F_m(x) = F_{m-1}(x) + \nu \gamma_m h_m(x)$$

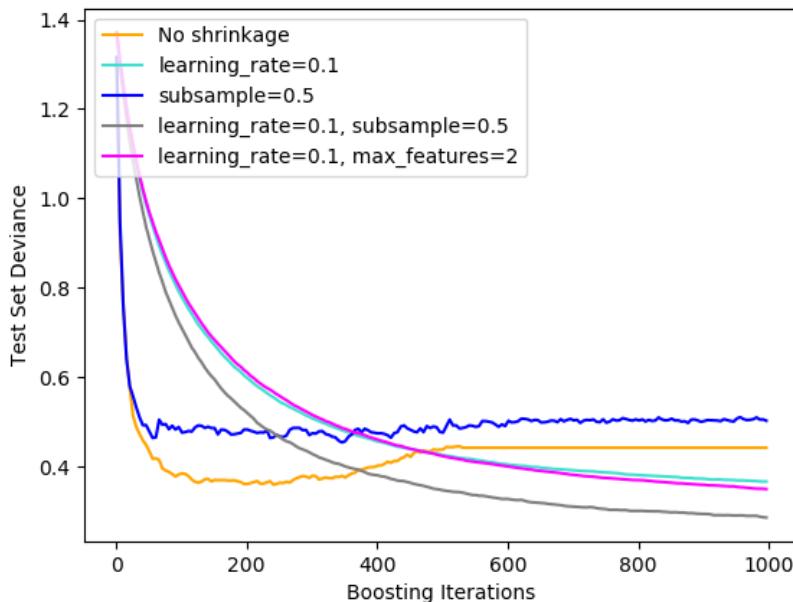

The parameter  $\nu$  is also called the **learning rate** because it scales the step length the gradient descent procedure; it can be set via the `learning_rate` parameter.

The parameter `learning_rate` strongly interacts with the parameter `n_estimators`, the number of weak learners to fit. Smaller values of `learning_rate` require larger numbers of weak learners to maintain a constant training error. Empirical evidence suggests that small values of `learning_rate` favor better test error. [\[HTF2009\]](#) recommend to set the learning rate to a small constant (e.g. `learning_rate <= 0.1`) and choose `n_estimators` by early stopping. For a more detailed discussion of the interaction between `learning_rate` and `n_estimators` see [\[R2007\]](#).

### Subsampling

[\[F1999\]](#) proposed stochastic gradient boosting, which combines gradient boosting with bootstrap averaging (bagging). At each iteration the base classifier is trained on a fraction `subsample` of the available training data. The subsample is drawn without replacement. A typical value of `subsample` is 0.5.

The figure below illustrates the effect of shrinkage and subsampling on the goodness-of-fit of the model. We can clearly see that shrinkage outperforms no-shrinkage. Subsampling with shrinkage can further increase the accuracy of the model. Subsampling without shrinkage, on the other hand, does poorly.

Another strategy to reduce the variance is by subsampling the features analogous to the random splits in `RandomForestClassifier`. The number of subsampled features can be controlled via the `max_features` parameter.

---

**Note:** Using a small `max_features` value can significantly decrease the runtime.

---

Stochastic gradient boosting allows to compute out-of-bag estimates of the test deviance by computing the improvement in deviance on the examples that are not included in the bootstrap sample (i.e. the out-of-bag examples). The improvements are stored in the attribute `oob_improvement_`. `oob_improvement_[i]` holds the improvement in terms of the loss on the OOB samples if you add the `i`-th stage to the current predictions. Out-of-bag estimates can be used for model selection, for example to determine the optimal number of iterations. OOB estimates are usually very pessimistic thus we recommend to use cross-validation instead and only use OOB if cross-validation is too time consuming.

**Examples:**

- [Gradient Boosting regularization](#)
- [Gradient Boosting Out-of-Bag estimates](#)
- [OOB Errors for Random Forests](#)

## Interpretation

Individual decision trees can be interpreted easily by simply visualizing the tree structure. Gradient boosting models, however, comprise hundreds of regression trees thus they cannot be easily interpreted by visual inspection of the individual trees. Fortunately, a number of techniques have been proposed to summarize and interpret gradient boosting models.

### Feature importance

Often features do not contribute equally to predict the target response; in many situations the majority of the features are in fact irrelevant. When interpreting a model, the first question usually is: what are those important features and how do they contributing in predicting the target response?

Individual decision trees intrinsically perform feature selection by selecting appropriate split points. This information can be used to measure the importance of each feature; the basic idea is: the more often a feature is used in the split points of a tree the more important that feature is. This notion of importance can be extended to decision tree ensembles by simply averaging the feature importance of each tree (see [Feature importance evaluation](#) for more details).

The feature importance scores of a fit gradient boosting model can be accessed via the `feature_importances_` property:

```
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier

>>> X, y = make_hastie_10_2(random_state=0)
>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
...     max_depth=1, random_state=0).fit(X, y)
>>> clf.feature_importances_
array([ 0.11,  0.1,  0.11, ...]
```

#### Examples:

- [Gradient Boosting regression](#)

## Partial dependence

Partial dependence plots (PDP) show the dependence between the target response and a set of ‘target’ features, marginalizing over the values of all other features (the ‘complement’ features). Intuitively, we can interpret the partial dependence as the expected target response<sup>1</sup> as a function of the ‘target’ features<sup>2</sup>.

Due to the limits of human perception the size of the target feature set must be small (usually, one or two) thus the target features are usually chosen among the most important features.

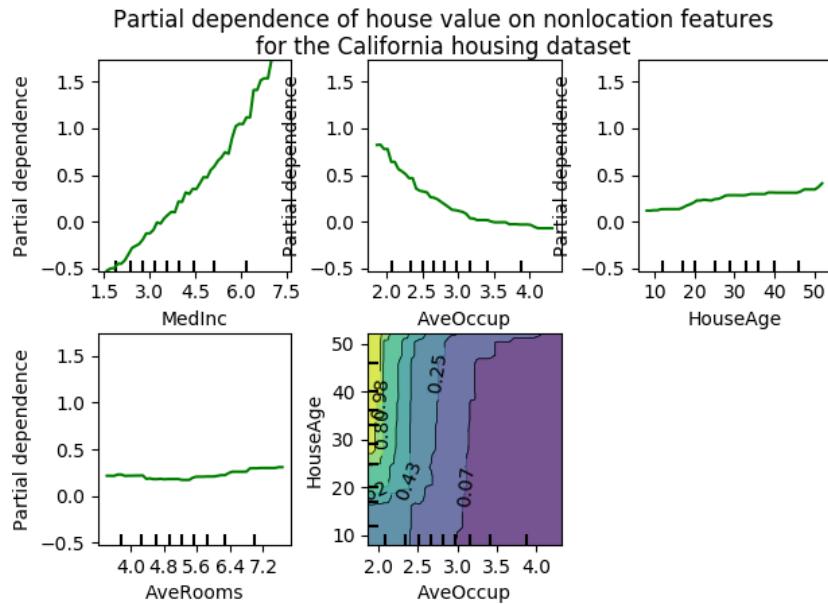

The Figure below shows four one-way and one two-way partial dependence plots for the California housing dataset:

One-way PDPs tell us about the interaction between the target response and the target feature (e.g. linear, non-linear). The upper left plot in the above Figure shows the effect of the median income in a district on the median house price; we can clearly see a linear relationship among them.

PDPs with two target features show the interactions among the two features. For example, the two-variable PDP in the above Figure shows the dependence of median house price on joint values of house age and avg. occupants per

<sup>1</sup> For classification with `loss='deviance'` the target response is  $\text{logit}(p)$ .

<sup>2</sup> More precisely its the expectation of the target response after accounting for the initial model; partial dependence plots do not include the `init` model.

household. We can clearly see an interaction between the two features: For an avg. occupancy greater than two, the house price is nearly independent of the house age, whereas for values less than two there is a strong dependence on age.

The module `partial_dependence` provides a convenience function `plot_partial_dependence` to create one-way and two-way partial dependence plots. In the below example we show how to create a grid of partial dependence plots: two one-way PDPs for the features 0 and 1 and a two-way PDP between the two features:

```
>>> from sklearn.datasets import make_hastie_10_2
>>> from sklearn.ensemble import GradientBoostingClassifier
>>> from sklearn.ensemble.partial_dependence import plot_partial_dependence

>>> X, y = make_hastie_10_2(random_state=0)
>>> clf = GradientBoostingClassifier(n_estimators=100, learning_rate=1.0,
...     max_depth=1, random_state=0).fit(X, y)
>>> features = [0, 1, (0, 1)]
>>> fig, axs = plot_partial_dependence(clf, X, features)
```

For multi-class models, you need to set the class label for which the PDPs should be created via the `label` argument:

```
>>> from sklearn.datasets import load_iris
>>> iris = load_iris()
>>> mc_clf = GradientBoostingClassifier(n_estimators=10,
...     max_depth=1).fit(iris.data, iris.target)
>>> features = [3, 2, (3, 2)]
>>> fig, axs = plot_partial_dependence(mc_clf, X, features, label=0)
```

If you need the raw values of the partial dependence function rather than the plots you can use the `partial_dependence` function:

```
>>> from sklearn.ensemble.partial_dependence import partial_dependence

>>> pdp, axes = partial_dependence(clf, [0], X=X)
>>> pdp
array([[ 2.46643157,  2.46643157, ...
```

```
>>> axes  
[array([-1.62497054, -1.59201391, ...
```

The function requires either the argument `grid` which specifies the values of the target features on which the partial dependence function should be evaluated or the argument `X` which is a convenience mode for automatically creating `grid` from the training data. If `X` is given, the `axes` value returned by the function gives the axis for each target feature.

For each value of the ‘target’ features in the `grid` the partial dependence function need to marginalize the predictions of a tree over all possible values of the ‘complement’ features. In decision trees this function can be evaluated efficiently without reference to the training data. For each grid point a weighted tree traversal is performed: if a split node involves a ‘target’ feature, the corresponding left or right branch is followed, otherwise both branches are followed, each branch is weighted by the fraction of training samples that entered that branch. Finally, the partial dependence is given by a weighted average of all visited leaves. For tree ensembles the results of each individual tree are again averaged.

### Examples:

- *Partial Dependence Plots*

## VotingClassifier

The idea behind the voting classifier implementation is to combine conceptually different machine learning classifiers and use a majority vote or the average predicted probabilities (soft vote) to predict the class labels. Such a classifier can be useful for a set of equally well performing model in order to balance out their individual weaknesses.

### Majority Class Labels (Majority/Hard Voting)

In majority voting, the predicted class label for a particular sample is the class label that represents the majority (mode) of the class labels predicted by each individual classifier.

E.g., if the prediction for a given sample is

- classifier 1 -> class 1
- classifier 2 -> class 1
- classifier 3 -> class 2

the `VotingClassifier` (with `voting='hard'`) would classify the sample as “class 1” based on the majority class label.

In the cases of a tie, the `VotingClassifier` will select the class based on the ascending sort order. E.g., in the following scenario

- classifier 1 -> class 2
- classifier 2 -> class 1

the class label 1 will be assigned to the sample.

## Usage

The following example shows how to fit the majority rule classifier:

```
>>> from sklearn import datasets
>>> from sklearn.model_selection import cross_val_score
>>> from sklearn.linear_model import LogisticRegression
>>> from sklearn.naive_bayes import GaussianNB
>>> from sklearn.ensemble import RandomForestClassifier
>>> from sklearn.ensemble import VotingClassifier

>>> iris = datasets.load_iris()
>>> X, y = iris.data[:, 1:3], iris.target

>>> clf1 = LogisticRegression(random_state=1)
>>> clf2 = RandomForestClassifier(random_state=1)
>>> clf3 = GaussianNB()

>>> eclf = VotingClassifier(estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)], voting='hard')

>>> for clf, label in zip([clf1, clf2, clf3, eclf], ['Logistic Regression', 'Random Forest', 'naive Bayes', 'Ensemble']):
...     scores = cross_val_score(clf, X, y, cv=5, scoring='accuracy')
...     print("Accuracy: %0.2f (+/- %0.2f) [%s]" % (scores.mean(), scores.std(), label))
Accuracy: 0.90 (+/- 0.05) [Logistic Regression]
Accuracy: 0.93 (+/- 0.05) [Random Forest]
Accuracy: 0.91 (+/- 0.04) [naive Bayes]
Accuracy: 0.95 (+/- 0.05) [Ensemble]
```

## Weighted Average Probabilities (Soft Voting)

In contrast to majority voting (hard voting), soft voting returns the class label as argmax of the sum of predicted probabilities.

Specific weights can be assigned to each classifier via the `weights` parameter. When weights are provided, the predicted class probabilities for each classifier are collected, multiplied by the classifier weight, and averaged. The final class label is then derived from the class label with the highest average probability.

To illustrate this with a simple example, let's assume we have 3 classifiers and a 3-class classification problems where we assign equal weights to all classifiers:  $w_1=1$ ,  $w_2=1$ ,  $w_3=1$ .

The weighted average probabilities for a sample would then be calculated as follows:

classifier	class 1	class 2	class 3
classifier 1	$w_1 * 0.2$	$w_1 * 0.5$	$w_1 * 0.3$
classifier 2	$w_2 * 0.6$	$w_2 * 0.3$	$w_2 * 0.1$
classifier 3	$w_3 * 0.3$	$w_3 * 0.4$	$w_3 * 0.3$
weighted average	0.37	0.4	0.23

Here, the predicted class label is 2, since it has the highest average probability.

The following example illustrates how the decision regions may change when a soft `VotingClassifier` is used based on an linear Support Vector Machine, a Decision Tree, and a K-nearest neighbor classifier:

```
>>> from sklearn import datasets
>>> from sklearn.tree import DecisionTreeClassifier
>>> from sklearn.neighbors import KNeighborsClassifier
>>> from sklearn.svm import SVC
>>> from itertools import product
>>> from sklearn.ensemble import VotingClassifier

>>> # Loading some example data
>>> iris = datasets.load_iris()
>>> X = iris.data[:, [0,2]]
>>> y = iris.target

>>> # Training classifiers
>>> clf1 = DecisionTreeClassifier(max_depth=4)
>>> clf2 = KNeighborsClassifier(n_neighbors=7)
>>> clf3 = SVC(kernel='rbf', probability=True)
>>> eclf = VotingClassifier(estimators=[('dt', clf1), ('knn', clf2), ('svc', clf3)], voting='soft', weights=[2,1,2])

>>> clf1 = clf1.fit(X,y)
>>> clf2 = clf2.fit(X,y)
>>> clf3 = clf3.fit(X,y)
>>> eclf = eclf.fit(X,y)
```

## Using the *VotingClassifier* with *GridSearch*

The *VotingClassifier* can also be used together with *GridSearch* in order to tune the hyperparameters of the individual estimators:

```
>>> from sklearn.model_selection import GridSearchCV
>>> clf1 = LogisticRegression(random_state=1)
>>> clf2 = RandomForestClassifier(random_state=1)
>>> clf3 = GaussianNB()
>>> eclf = VotingClassifier(estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)], voting='soft')

>>> params = {'lr__C': [1.0, 100.0], 'rf__n_estimators': [20, 200], }

>>> grid = GridSearchCV(estimator=eclf, param_grid=params, cv=5)
>>> grid = grid.fit(iris.data, iris.target)
```

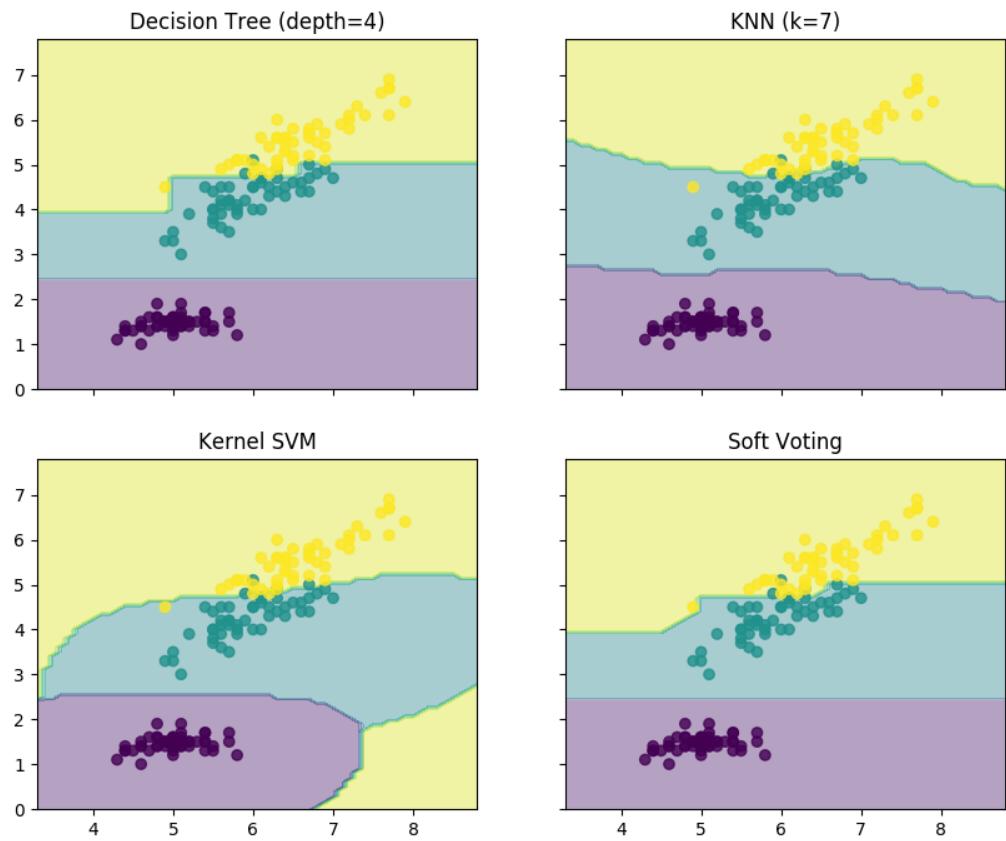

## Usage

In order to predict the class labels based on the predicted class-probabilities (scikit-learn estimators in the *VotingClassifier* must support `predict_proba` method):

```
>>> eclf = VotingClassifier(estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)], voting='soft')
```

Optionally, weights can be provided for the individual classifiers:

```
>>> eclf = VotingClassifier(estimators=[('lr', clf1), ('rf', clf2), ('gnb', clf3)], voting='soft', weights=[2,5,1])
```

### 3.1.12 Multiclass and multilabel algorithms

**Warning:** All classifiers in scikit-learn do multiclass classification out-of-the-box. You don't need to use the `sklearn.multiclass` module unless you want to experiment with different multiclass strategies.

The `sklearn.multiclass` module implements *meta-estimators* to solve multiclass and multilabel classification problems by decomposing such problems into binary classification problems. Multitarget regression is also supported.

- **Multiclass classification** means a classification task with more than two classes; e.g., classify a set of images of fruits which may be oranges, apples, or pears. Multiclass classification makes the assumption that each sample is assigned to one and only one label: a fruit can be either an apple or a pear but not both at the same time.
- **Multilabel classification** assigns to each sample a set of target labels. This can be thought as predicting properties of a data-point that are not mutually exclusive, such as topics that are relevant for a document. A text might be about any of religion, politics, finance or education at the same time or none of these.
- **Multioutput regression** assigns each sample a set of target values. This can be thought of as predicting several properties for each data-point, such as wind direction and magnitude at a certain location.
- **Multioutput-multiclass classification** and **multi-task classification** means that a single estimator has to handle several joint classification tasks. This is both a generalization of the multi-label classification task, which only considers binary classification, as well as a generalization of the multi-class classification task. *The output format is a 2d numpy array or sparse matrix.*

The set of labels can be different for each output variable. For instance, a sample could be assigned “pear” for an output variable that takes possible values in a finite set of species such as “pear”, “apple”; and “blue” or “green” for a second output variable that takes possible values in a finite set of colors such as “green”, “red”, “blue”, “yellow”...

This means that any classifiers handling multi-output multiclass or multi-task classification tasks, support the multi-label classification task as a special case. Multi-task classification is similar to the multi-output classification task with different model formulations. For more information, see the relevant estimator documentation.

All scikit-learn classifiers are capable of multiclass classification, but the meta-estimators offered by `sklearn.multiclass` permit changing the way they handle more than two classes because this may have an effect on classifier performance (either in terms of generalization error or required computational resources).

Below is a summary of the classifiers supported by scikit-learn grouped by strategy; you don't need the meta-estimators in this class if you're using one of these, unless you want custom multiclass behavior:

- Inherently multiclass: *Naive Bayes*, *LDA* and *QDA*, *Decision Trees*, *Random Forests*, *Nearest Neighbors*, setting `multi_class='multinomial'` in `sklearn.linear_model.LogisticRegression`.
- Support multilabel: *Decision Trees*, *Random Forests*, *Nearest Neighbors*.
- One-Vs-One: `sklearn.svm.SVC`.
- One-Vs-All: all linear models except `sklearn.svm.SVC`.

Some estimators also support multioutput-multiclass classification tasks *Decision Trees*, *Random Forests*, *Nearest Neighbors*.

**Warning:** At present, no metric in `sklearn.metrics` supports the multioutput-multiclass classification task.

## Multilabel classification format

In multilabel learning, the joint set of binary classification tasks is expressed with label binary indicator array: each sample is one row of a 2d array of shape (n\_samples, n\_classes) with binary values: the one, i.e. the non zero elements, corresponds to the subset of labels. An array such as `np.array([[1, 0, 0], [0, 1, 1], [0, 0, 0]])` represents label 0 in the first sample, labels 1 and 2 in the second sample, and no labels in the third sample.

Producing multilabel data as a list of sets of labels may be more intuitive. The `MultiLabelBinarizer` transformer can be used to convert between a collection of collections of labels and the indicator format.

```
>>> from sklearn.preprocessing import MultiLabelBinarizer
>>> y = [[2, 3, 4], [2], [0, 1, 3], [0, 1, 2, 3, 4], [0, 1, 2]]
>>> MultiLabelBinarizer().fit_transform(y)
array([[0, 0, 1, 1, 1],
       [0, 0, 1, 0, 0],
       [1, 1, 0, 1, 0],
       [1, 1, 1, 1, 1],
       [1, 1, 1, 0, 0]])
```

## One-Vs-The-Rest

This strategy, also known as **one-vs-all**, is implemented in `OneVsRestClassifier`. The strategy consists in fitting one classifier per class. For each classifier, the class is fitted against all the other classes. In addition to its computational efficiency (only  $n_{classes}$  classifiers are needed), one advantage of this approach is its interpretability. Since each class is represented by one and only one classifier, it is possible to gain knowledge about the class by inspecting its corresponding classifier. This is the most commonly used strategy and is a fair default choice.

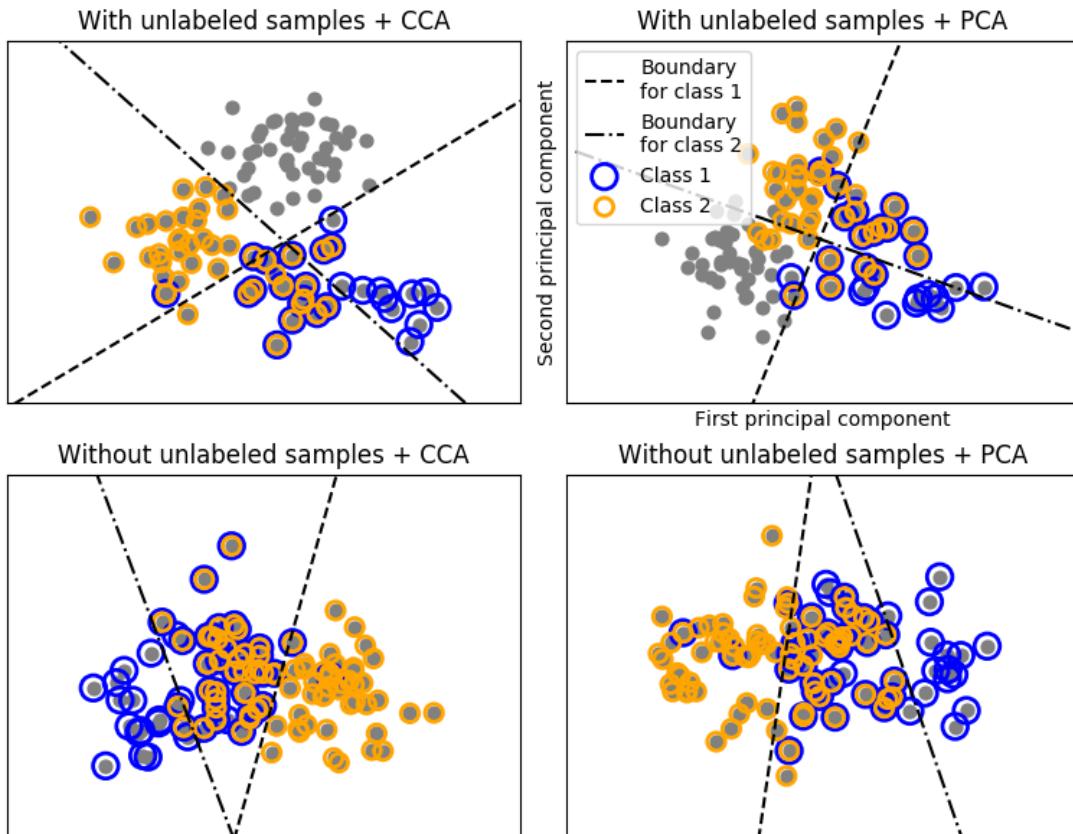

## Multiclass learning

Below is an example of multiclass learning using OvR:

```
>>> from sklearn import datasets
>>> from sklearn.multiclass import OneVsRestClassifier
>>> from sklearn.svm import LinearSVC
>>> iris = datasets.load_iris()
>>> X, y = iris.data, iris.target
>>> OneVsRestClassifier(LinearSVC(random_state=0)).fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
       1, 2, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 2, 2, 1, 1, 1, 1, 1, 1, 1, 1,
       1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
       2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
```

## Multilabel learning

`OneVsRestClassifier` also supports multilabel classification. To use this feature, feed the classifier an indicator matrix, in which cell [i, j] indicates the presence of label j in sample i.

### Examples:

- *Multilabel classification*

## One-Vs-One

`OneVsOneClassifier` constructs one classifier per pair of classes. At prediction time, the class which received the most votes is selected. In the event of a tie (among two classes with an equal number of votes), it selects the class with the highest aggregate classification confidence by summing over the pair-wise classification confidence levels computed by the underlying binary classifiers.

Since it requires to fit  $n_{\text{classes}} * (n_{\text{classes}} - 1) / 2$  classifiers, this method is usually slower than one-vs-the-rest, due to its  $O(n_{\text{classes}}^2)$  complexity. However, this method may be advantageous for algorithms such as kernel algorithms which don't scale well with  $n_{\text{samples}}$ . This is because each individual learning problem only involves a small subset of the data whereas, with one-vs-the-rest, the complete dataset is used  $n_{\text{classes}}$  times.

## Multiclass learning

Below is an example of multiclass learning using OvO:

```
>>> from sklearn import datasets
>>> from sklearn.multiclass import OneVsOneClassifier
>>> from sklearn.svm import LinearSVC
```

```
>>> iris = datasets.load_iris()
>>> X, y = iris.data, iris.target
>>> OneVsOneClassifier(LinearSVC(random_state=0)).fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
       0, 0, 0, 0, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
       1, 2, 1, 2, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1, 1,
       1, 1, 1, 1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
       2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2,
```

### Error-Correcting Output-Codes

Output-code based strategies are fairly different from one-vs-the-rest and one-vs-one. With these strategies, each class is represented in a Euclidean space, where each dimension can only be 0 or 1. Another way to put it is that each class is represented by a binary code (an array of 0 and 1). The matrix which keeps track of the location/code of each class is called the code book. The code size is the dimensionality of the aforementioned space. Intuitively, each class should be represented by a code as unique as possible and a good code book should be designed to optimize classification accuracy. In this implementation, we simply use a randomly-generated code book as advocated in<sup>3</sup> although more elaborate methods may be added in the future.

At fitting time, one binary classifier per bit in the code book is fitted. At prediction time, the classifiers are used to project new points in the class space and the class closest to the points is chosen.

In `OutputCodeClassifier`, the `code_size` attribute allows the user to control the number of classifiers which will be used. It is a percentage of the total number of classes.

A number between 0 and 1 will require fewer classifiers than one-vs-the-rest. In theory, `log2(n_classes) / n_classes` is sufficient to represent each class unambiguously. However, in practice, it may not lead to good accuracy since `log2(n_classes)` is much smaller than `n_classes`.

A number greater than 1 will require more classifiers than one-vs-the-rest. In this case, some classifiers will in theory correct for the mistakes made by other classifiers, hence the name “error-correcting”. In practice, however, this may not happen as classifier mistakes will typically be correlated. The error-correcting output codes have a similar effect to bagging.

### Multiclass learning

Below is an example of multiclass learning using Output-Codes:

```
>>> from sklearn import datasets
>>> from sklearn.multiclass import OutputCodeClassifier
>>> from sklearn.svm import LinearSVC
>>> iris = datasets.load_iris()
>>> X, y = iris.data, iris.target
>>> clf = OutputCodeClassifier(LinearSVC(random_state=0),
...                             code_size=2, random_state=0)
>>> clf.fit(X, y).predict(X)
array([0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0, 0,
```

<sup>3</sup> “The error coding method and PICTs”, James G., Hastie T., Journal of Computational and Graphical statistics 7, 1998.

## Multioutput regression

Multioutput regression support can be added to any regressor with `MultiOutputRegressor`. This strategy consists of fitting one regressor per target. Since each target is represented by exactly one regressor it is possible to gain knowledge about the target by inspecting its corresponding regressor. As `MultiOutputRegressor` fits one regressor per target it can not take advantage of correlations between targets.

Below is an example of multioutput regression:

```
>>> from sklearn.datasets import make_regression
>>> from sklearn.multioutput import MultiOutputRegressor
>>> from sklearn.ensemble import GradientBoostingRegressor
>>> X, y = make_regression(n_samples=10, n_targets=3, random_state=1)
>>> MultiOutputRegressor(GradientBoostingRegressor(random_state=0)).fit(X, y).predict(X)
array([[-154.75474165, -147.03498585, -50.03812219],
       [ 7.12165031,   5.12914884,  -81.46081961],
       [-187.8948621, -100.44373091,  13.88978285],
       [-141.62745778,  95.02891072, -191.48204257],
       [ 97.03260883, 165.34867495, 139.52003279],
       [ 123.92529176, 21.25719016,  -7.84253  ],
       [-122.25193977, -85.16443186, -107.12274212],
       [-30.170388,   -94.80956739,  12.16979946],
       [ 140.72667194, 176.50941682, -17.50447799],
       [ 149.37967282, -81.15699552,  -5.72850319]])
```

## Multioutput classification

Multioutput classification support can be added to any classifier with `MultiOutputClassifier`. This strategy consists of fitting one classifier per target. This allows multiple target variable classifications. The purpose of this class is to extend estimators to be able to estimate a series of target functions ( $f_1, f_2, f_3, \dots, f_n$ ) that are trained on a single  $X$  predictor matrix to predict a series of responses ( $y_1, y_2, y_3, \dots, y_n$ ).

Below is an example of multioutput classification:

```
>>> from sklearn.datasets import make_classification  
>>> from sklearn.multioutput import MultiOutputClassifier  
>>> from sklearn.ensemble import RandomForestClassifier  
>>> from sklearn.utils import shuffle  
>>> import numpy as np  
>>> X, y1 = make_classification(n_samples=10, n_features=100, n_informative=30, n_  
    ↴classes=3, random_state=1)  
>>> y2 = shuffle(y1, random_state=1)  
>>> y3 = shuffle(y1, random_state=2)
```

```
>>> Y = np.vstack((y1, y2, y3)).T
>>> n_samples, n_features = X.shape # 10,100
>>> n_outputs = Y.shape[1] # 3
>>> n_classes = 3
>>> forest = RandomForestClassifier(n_estimators=100, random_state=1)
>>> multi_target_forest = MultiOutputClassifier(forest, n_jobs=-1)
>>> multi_target_forest.fit(X, Y).predict(X)
array([[2, 2, 0],
       [1, 2, 1],
       [2, 1, 0],
       [0, 0, 2],
       [0, 2, 1],
       [0, 0, 2],
       [1, 1, 0],
       [1, 1, 1],
       [0, 0, 2],
       [2, 0, 0]])
```

### 3.1.13 Feature selection

The classes in the `sklearn.feature_selection` module can be used for feature selection/dimensionality reduction on sample sets, either to improve estimators' accuracy scores or to boost their performance on very high-dimensional datasets.

#### Removing features with low variance

`VarianceThreshold` is a simple baseline approach to feature selection. It removes all features whose variance doesn't meet some threshold. By default, it removes all zero-variance features, i.e. features that have the same value in all samples.

As an example, suppose that we have a dataset with boolean features, and we want to remove all features that are either one or zero (on or off) in more than 80% of the samples. Boolean features are Bernoulli random variables, and the variance of such variables is given by

$$\text{Var}[X] = p(1 - p)$$

so we can select using the threshold `.8 * (1 - .8)`:

```
>>> from sklearn.feature_selection import VarianceThreshold
>>> X = [[0, 0, 1], [0, 1, 0], [1, 0, 0], [0, 1, 1], [0, 1, 0], [0, 1, 1]]
>>> sel = VarianceThreshold(threshold=(.8 * (1 - .8)))
>>> sel.fit_transform(X)
array([[0, 1],
       [1, 0],
       [0, 0],
       [1, 1],
       [1, 0],
       [1, 1]])
```

As expected, `VarianceThreshold` has removed the first column, which has a probability  $p = 5/6 > .8$  of containing a zero.

## Univariate feature selection

Univariate feature selection works by selecting the best features based on univariate statistical tests. It can be seen as a preprocessing step to an estimator. Scikit-learn exposes feature selection routines as objects that implement the `transform` method:

- `SelectKBest` removes all but the  $k$  highest scoring features
- `SelectPercentile` removes all but a user-specified highest scoring percentage of features
- using common univariate statistical tests for each feature: false positive rate `SelectFpr`, false discovery rate `SelectFdr`, or family wise error `SelectFwe`.
- `GenericUnivariateSelect` allows to perform univariate feature selection with a configurable strategy. This allows to select the best univariate selection strategy with hyper-parameter search estimator.

For instance, we can perform a  $\chi^2$  test to the samples to retrieve only the two best features as follows:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectKBest
>>> from sklearn.feature_selection import chi2
>>> iris = load_iris()
>>> X, y = iris.data, iris.target
>>> X.shape
(150, 4)
>>> X_new = SelectKBest(chi2, k=2).fit_transform(X, y)
>>> X_new.shape
(150, 2)
```

These objects take as input a scoring function that returns univariate scores and p-values (or only scores for `SelectKBest` and `SelectPercentile`):

- For regression: `f_regression`, `mutual_info_regression`
- For classification: `chi2`, `f_classif`, `mutual_info_classif`

The methods based on F-test estimate the degree of linear dependency between two random variables. On the other hand, mutual information methods can capture any kind of statistical dependency, but being nonparametric, they require more samples for accurate estimation.

### Feature selection with sparse data

If you use sparse data (i.e. data represented as sparse matrices), `chi2`, `mutual_info_regression`, `mutual_info_classif` will deal with the data without making it dense.

**Warning:** Beware not to use a regression scoring function with a classification problem, you will get useless results.

### Examples:

- [Univariate Feature Selection](#)
- [Comparison of F-test and mutual information](#)

## Recursive feature elimination

Given an external estimator that assigns weights to features (e.g., the coefficients of a linear model), recursive feature elimination (`RFE`) is to select features by recursively considering smaller and smaller sets of features. First, the estimator is trained on the initial set of features and weights are assigned to each one of them. Then, features whose absolute weights are the smallest are pruned from the current set features. That procedure is recursively repeated on the pruned set until the desired number of features to select is eventually reached.

`RFEcv` performs RFE in a cross-validation loop to find the optimal number of features.

### Examples:

- *Recursive feature elimination*: A recursive feature elimination example showing the relevance of pixels in a digit classification task.
- *Recursive feature elimination with cross-validation*: A recursive feature elimination example with automatic tuning of the number of features selected with cross-validation.

## Feature selection using SelectFromModel

`SelectFromModel` is a meta-transformer that can be used along with any estimator that has a `coef_` or `feature_importances_` attribute after fitting. The features are considered unimportant and removed, if the corresponding `coef_` or `feature_importances_` values are below the provided `threshold` parameter. Apart from specifying the threshold numerically, there are built-in heuristics for finding a threshold using a string argument. Available heuristics are “mean”, “median” and float multiples of these like “0.1\*mean”.

For examples on how it is to be used refer to the sections below.

### Examples

- *Feature selection using SelectFromModel and LassoCV*: Selecting the two most important features from the Boston dataset without knowing the threshold beforehand.

## L1-based feature selection

*Linear models* penalized with the L1 norm have sparse solutions: many of their estimated coefficients are zero. When the goal is to reduce the dimensionality of the data to use with another classifier, they can be used along with `feature_selection.SelectFromModel` to select the non-zero coefficients. In particular, sparse estimators useful for this purpose are the `linear_model.Lasso` for regression, and of `linear_model.LogisticRegression` and `svm.LinearSVC` for classification:

```
>>> from sklearn.svm import LinearSVC
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectFromModel
>>> iris = load_iris()
>>> X, y = iris.data, iris.target
>>> X.shape
(150, 4)
>>> lsvc = LinearSVC(C=0.01, penalty="l1", dual=False).fit(X, y)
>>> model = SelectFromModel(lsvc, prefit=True)
>>> X_new = model.transform(X)
```

```
>>> X_new.shape
(150, 3)
```

With SVMs and logistic-regression, the parameter C controls the sparsity: the smaller C the fewer features selected. With Lasso, the higher the alpha parameter, the fewer features selected.

### Examples:

- *Classification of text documents using sparse features*: Comparison of different algorithms for document classification including L1-based feature selection.

## L1-recovery and compressive sensing

For a good choice of alpha, the *Lasso* can fully recover the exact set of non-zero variables using only few observations, provided certain specific conditions are met. In particular, the number of samples should be “sufficiently large”, or L1 models will perform at random, where “sufficiently large” depends on the number of non-zero coefficients, the logarithm of the number of features, the amount of noise, the smallest absolute value of non-zero coefficients, and the structure of the design matrix X. In addition, the design matrix must display certain specific properties, such as not being too correlated.

There is no general rule to select an alpha parameter for recovery of non-zero coefficients. It can be set by cross-validation (*LassoCV* or *LassoLarsCV*), though this may lead to under-penalized models: including a small number of non-relevant variables is not detrimental to prediction score. BIC (*LassoLarsIC*) tends, on the opposite, to set high values of alpha.

## Randomized sparse models

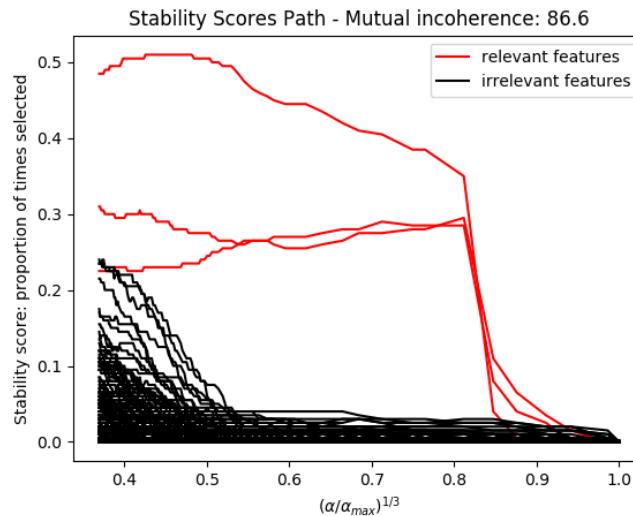

In terms of feature selection, there are some well-known limitations of L1-penalized models for regression and classification. For example, it is known that the Lasso will tend to select an individual variable out of a group of highly correlated features. Furthermore, even when the correlation between features is not too high, the conditions under which L1-penalized methods consistently select “good” features can be restrictive in general.

To mitigate this problem, it is possible to use randomization techniques such as those presented in [B2009] and [M2010]. The latter technique, known as stability selection, is implemented in the module `sklearn.linear_model`. In the stability selection method, a subsample of the data is fit to a L1-penalized model where the penalty of a random subset of coefficients has been scaled. Specifically, given a subsample of the data  $(x_i, y_i), i \in I$ , where  $I \subset \{1, 2, \dots, n\}$  is a random subset of the data of size  $n_I$ , the following modified Lasso fit is obtained:

$$\hat{w}_I = \arg \min_w \frac{1}{2n_I} \sum_{i \in I} (y_i - x_i^T w)^2 + \alpha \sum_{j=1}^p \frac{|w_j|}{s_j},$$

where  $s_j \in \{s, 1\}$  are independent trials of a fair Bernoulli random variable, and  $0 < s < 1$  is the scaling factor. By repeating this procedure across different random subsamples and Bernoulli trials, one can count the fraction of times the randomized procedure selected each feature, and used these fractions as scores for feature selection.

`RandomizedLasso` implements this strategy for regression settings, using the Lasso, while `RandomizedLogisticRegression` uses the logistic regression and is suitable for classification tasks. To get a full path of stability scores you can use `lasso_stability_path`.

Note that for randomized sparse models to be more powerful than standard F statistics at detecting non-zero features, the ground truth model should be sparse, in other words, there should be only a small fraction of features non zero.

### Tree-based feature selection

Tree-based estimators (see the `sklearn.tree` module and forest of trees in the `sklearn.ensemble` module) can be used to compute feature importances, which in turn can be used to discard irrelevant features (when coupled with the `sklearn.feature_selection.SelectFromModel` meta-transformer):

```
>>> from sklearn.ensemble import ExtraTreesClassifier
>>> from sklearn.datasets import load_iris
>>> from sklearn.feature_selection import SelectFromModel
>>> iris = load_iris()
>>> X, y = iris.data, iris.target
>>> X.shape
(150, 4)
>>> clf = ExtraTreesClassifier()
>>> clf = clf.fit(X, y)
>>> clf.feature_importances_
array([ 0.04...,  0.05...,  0.4...,  0.4...])
>>> model = SelectFromModel(clf, prefit=True)
>>> X_new = model.transform(X)
>>> X_new.shape
(150, 2)
```

**Examples:**

- *Feature importances with forests of trees*: example on synthetic data showing the recovery of the actually meaningful features.
- *Pixel importances with a parallel forest of trees*: example on face recognition data.

## Feature selection as part of a pipeline

Feature selection is usually used as a pre-processing step before doing the actual learning. The recommended way to do this in scikit-learn is to use a `sklearn.pipeline.Pipeline`:

```
clf = Pipeline([
    ('feature_selection', SelectFromModel(LinearSVC(penalty="l1"))),
    ('classification', RandomForestClassifier())
])
clf.fit(X, y)
```

In this snippet we make use of a `sklearn.svm.LinearSVC` coupled with `sklearn.feature_selection.SelectFromModel` to evaluate feature importances and select the most relevant features. Then, a `sklearn.ensemble.RandomForestClassifier` is trained on the transformed output, i.e. using only relevant features. You can perform similar operations with the other feature selection methods and also classifiers that provide a way to evaluate feature importances of course. See the `sklearn.pipeline.Pipeline` examples for more details.

### 3.1.14 Semi-Supervised

Semi-supervised learning is a situation in which in your training data some of the samples are not labeled. The semi-supervised estimators in `sklearn.semi_supervised` are able to make use of this additional unlabeled data to better capture the shape of the underlying data distribution and generalize better to new samples. These algorithms can perform well when we have a very small amount of labeled points and a large amount of unlabeled points.

**Unlabeled entries in y**

It is important to assign an identifier to unlabeled points along with the labeled data when training the model with the `fit` method. The identifier that this implementation uses is the integer value `-1`.

## Label Propagation

Label propagation denotes a few variations of semi-supervised graph inference algorithms.

**A few features available in this model:**

- Can be used for classification and regression tasks
- Kernel methods to project data into alternate dimensional spaces

`scikit-learn` provides two label propagation models: `LabelPropagation` and `LabelSpreading`. Both work by constructing a similarity graph over all items in the input dataset.

`LabelPropagation` and `LabelSpreading` differ in modifications to the similarity matrix that graph and the clamping effect on the label distributions. Clamping allows the algorithm to change the weight of the true ground labeled data to some degree. The `LabelPropagation` algorithm performs hard clamping of input labels, which

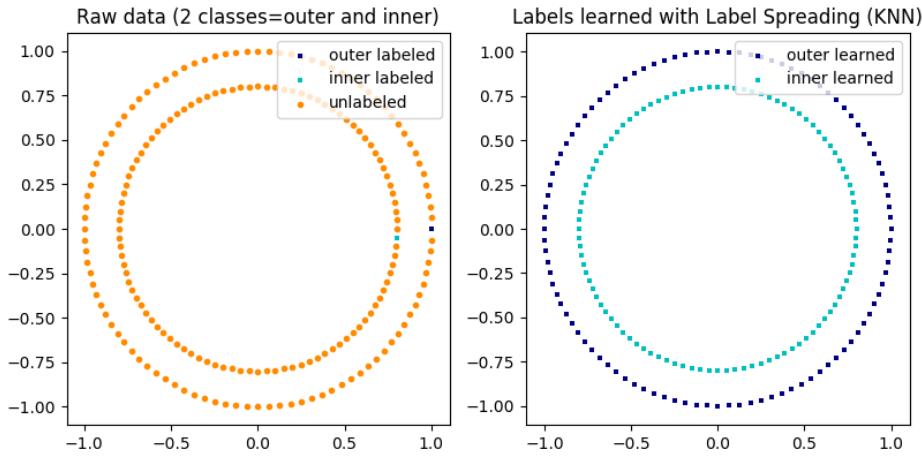

Fig. 3.1: **An illustration of label-propagation:** the structure of unlabeled observations is consistent with the class structure, and thus the class label can be propagated to the unlabeled observations of the training set.

means  $\alpha = 1$ . This clamping factor can be relaxed, to say  $\alpha = 0.8$ , which means that we will always retain 80 percent of our original label distribution, but the algorithm gets to change its confidence of the distribution within 20 percent.

`LabelPropagation` uses the raw similarity matrix constructed from the data with no modifications. In contrast, `LabelSpreading` minimizes a loss function that has regularization properties, as such it is often more robust to noise. The algorithm iterates on a modified version of the original graph and normalizes the edge weights by computing the normalized graph Laplacian matrix. This procedure is also used in `Spectral clustering`.

Label propagation models have two built-in kernel methods. Choice of kernel effects both scalability and performance of the algorithms. The following are available:

- rbf ( $\exp(-\gamma|x - y|^2)$ ,  $\gamma > 0$ ).  $\gamma$  is specified by keyword gamma.
- knn ( $1[x' \in kNN(x)]$ ).  $k$  is specified by keyword n\_neighbors.

The RBF kernel will produce a fully connected graph which is represented in memory by a dense matrix. This matrix may be very large and combined with the cost of performing a full matrix multiplication calculation for each iteration of the algorithm can lead to prohibitively long running times. On the other hand, the KNN kernel will produce a much more memory-friendly sparse matrix which can drastically reduce running times.

## Examples

### 3.1.15 Isotonic regression

The class `IsotonicRegression` fits a non-decreasing function to data. It solves the following problem:

$$\begin{aligned} & \text{minimize } \sum_i w_i (y_i - \hat{y}_i)^2 \\ & \text{subject to } \hat{y}_{\min} = \hat{y}_1 \leq \hat{y}_2 \dots \leq \hat{y}_n = \hat{y}_{\max} \end{aligned}$$

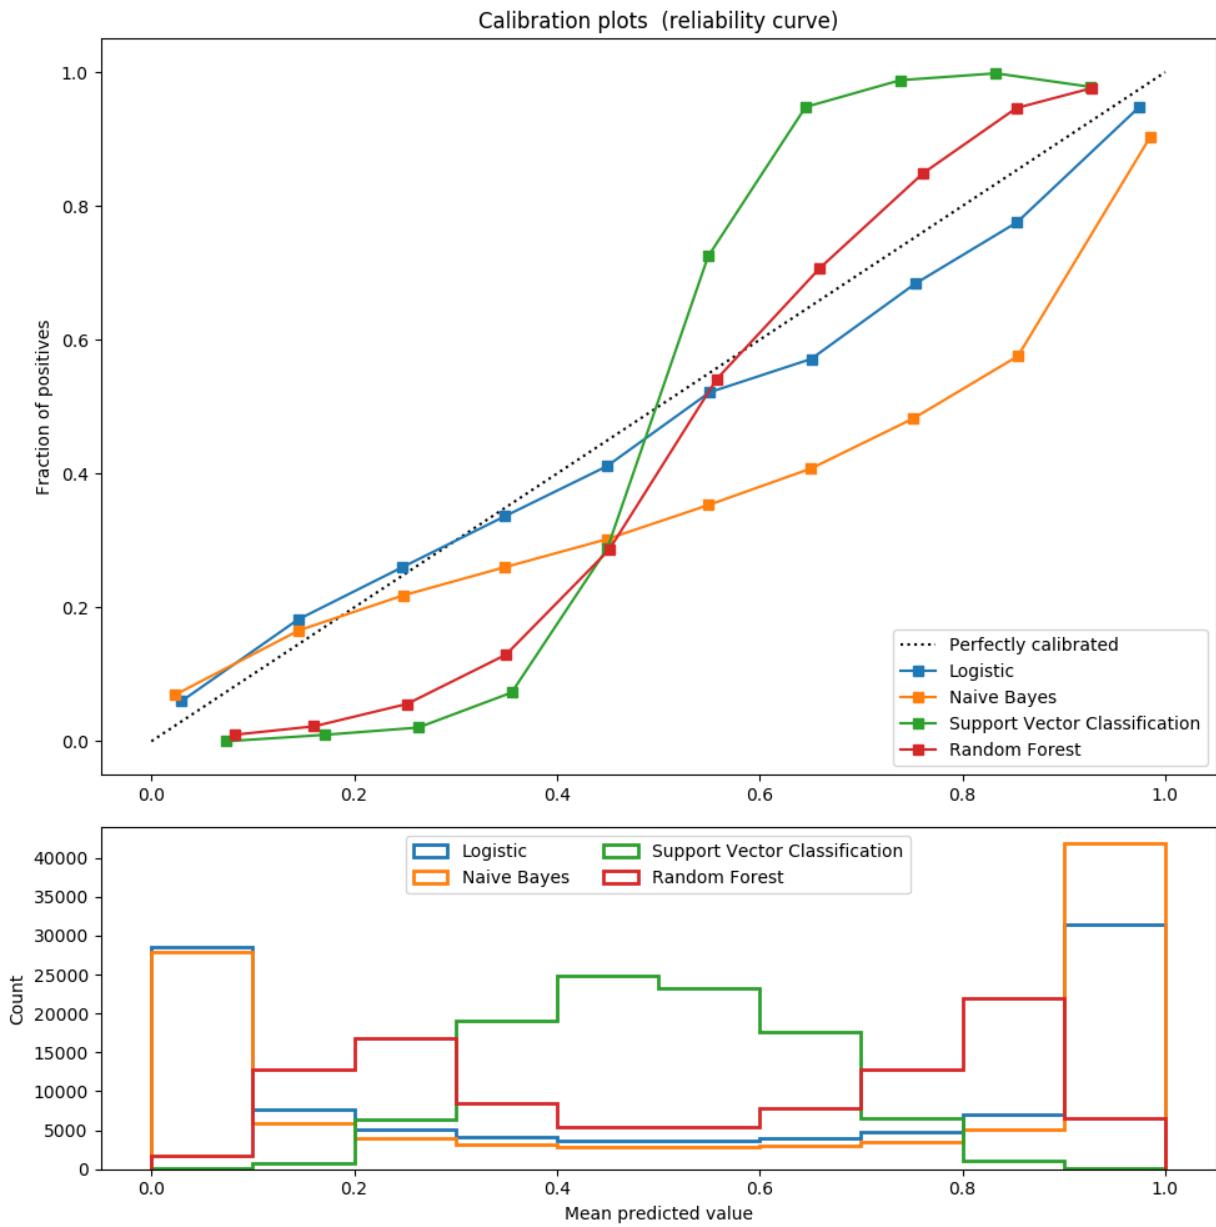

where each  $w_i$  is strictly positive and each  $y_i$  is an arbitrary real number. It yields the vector which is composed of non-decreasing elements the closest in terms of mean squared error. In practice this list of elements forms a function that is piecewise linear.

### 3.1.16 Probability calibration

When performing classification you often want not only to predict the class label, but also obtain a probability of the respective label. This probability gives you some kind of confidence on the prediction. Some models can give you poor estimates of the class probabilities and some even do not support probability prediction. The calibration module allows you to better calibrate the probabilities of a given model, or to add support for probability prediction.

Well calibrated classifiers are probabilistic classifiers for which the output of the `predict_proba` method can be directly interpreted as a confidence level. For instance, a well calibrated (binary) classifier should classify the samples such that among the samples to which it gave a `predict_proba` value close to 0.8, approximately 80% actually belong to the positive class. The following plot compares how well the probabilistic predictions of different classifiers are calibrated:

*LogisticRegression* returns well calibrated predictions by default as it directly optimizes log-loss. In contrast, the other methods return biased probabilities; with different biases per method:

- *GaussianNB* tends to push probabilities to 0 or 1 (note the counts in the histograms). This is mainly because it makes the assumption that features are conditionally independent given the class, which is not the case in this dataset which contains 2 redundant features.
- *RandomForestClassifier* shows the opposite behavior: the histograms show peaks at approximately 0.2 and 0.9 probability, while probabilities close to 0 or 1 are very rare. An explanation for this is given by Niculescu-Mizil and Caruana [4]: “Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values. Because predictions are restricted to the interval [0,1], errors caused by variance tend to be one-sided near zero and one. For example, if a model should predict  $p = 0$  for a case, the only way bagging can achieve this is if all bagged trees predict zero. If we add noise to the trees that bagging is averaging over, this noise will cause some trees to predict values larger than 0 for this case, thus moving the average prediction of the bagged ensemble away from 0. We observe this effect most strongly with random forests because the base-level trees trained with random forests have relatively high variance due to feature subsetting.” As a result, the calibration curve also referred to as the reliability diagram (Wilks 1995[5]) shows a characteristic sigmoid shape, indicating that the classifier could trust its “intuition” more and return probabilities closer to 0 or 1 typically.
- Linear Support Vector Classification (*LinearSVC*) shows an even more sigmoid curve as the RandomForestClassifier, which is typical for maximum-margin methods (compare Niculescu-Mizil and Caruana [4]), which focus on hard samples that are close to the decision boundary (the support vectors).

Two approaches for performing calibration of probabilistic predictions are provided: a parametric approach based on Platt’s sigmoid model and a non-parametric approach based on isotonic regression (*sklearn.isotonic*). Probability calibration should be done on new data not used for model fitting. The class *CalibratedClassifierCV* uses a cross-validation generator and estimates for each split the model parameter on the train samples and the calibration of the test samples. The probabilities predicted for the folds are then averaged. Already fitted classifiers can be calibrated by *CalibratedClassifierCV* via the parameter `cv="prefit"`. In this case, the user has to take care manually that data for model fitting and calibration are disjoint.

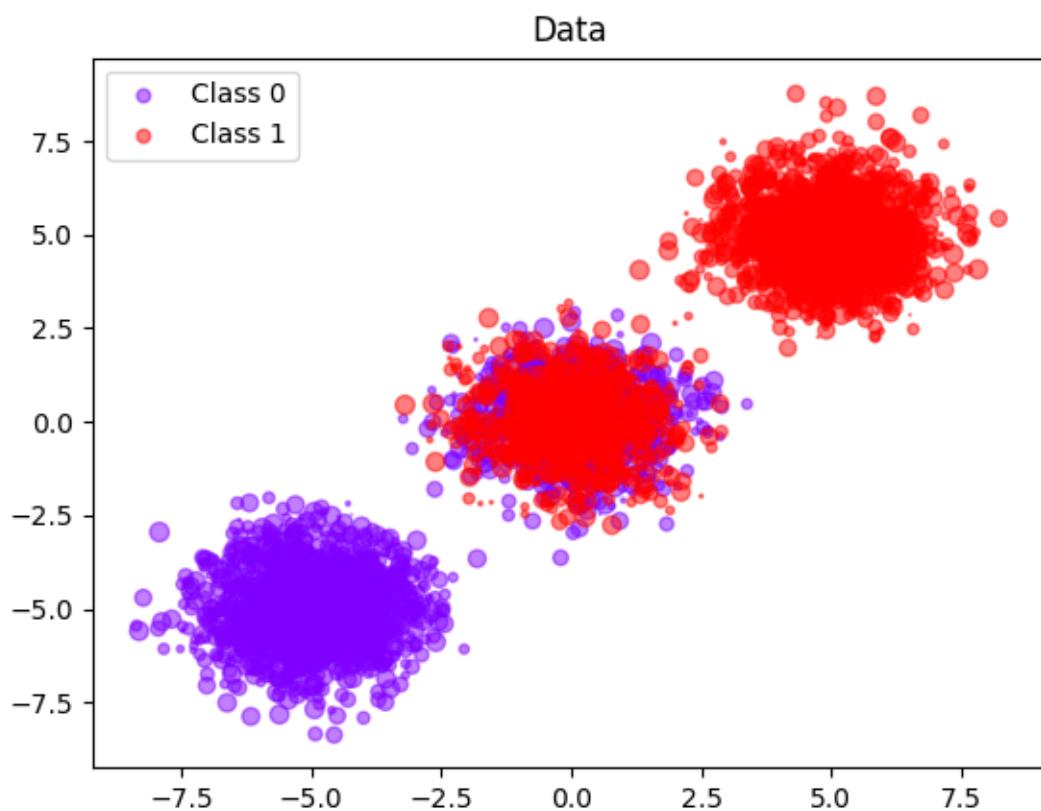

The following images demonstrate the benefit of probability calibration. The first image present a dataset with 2 classes and 3 blobs of data. The blob in the middle contains random samples of each class. The probability for the samples in this blob should be 0.5.

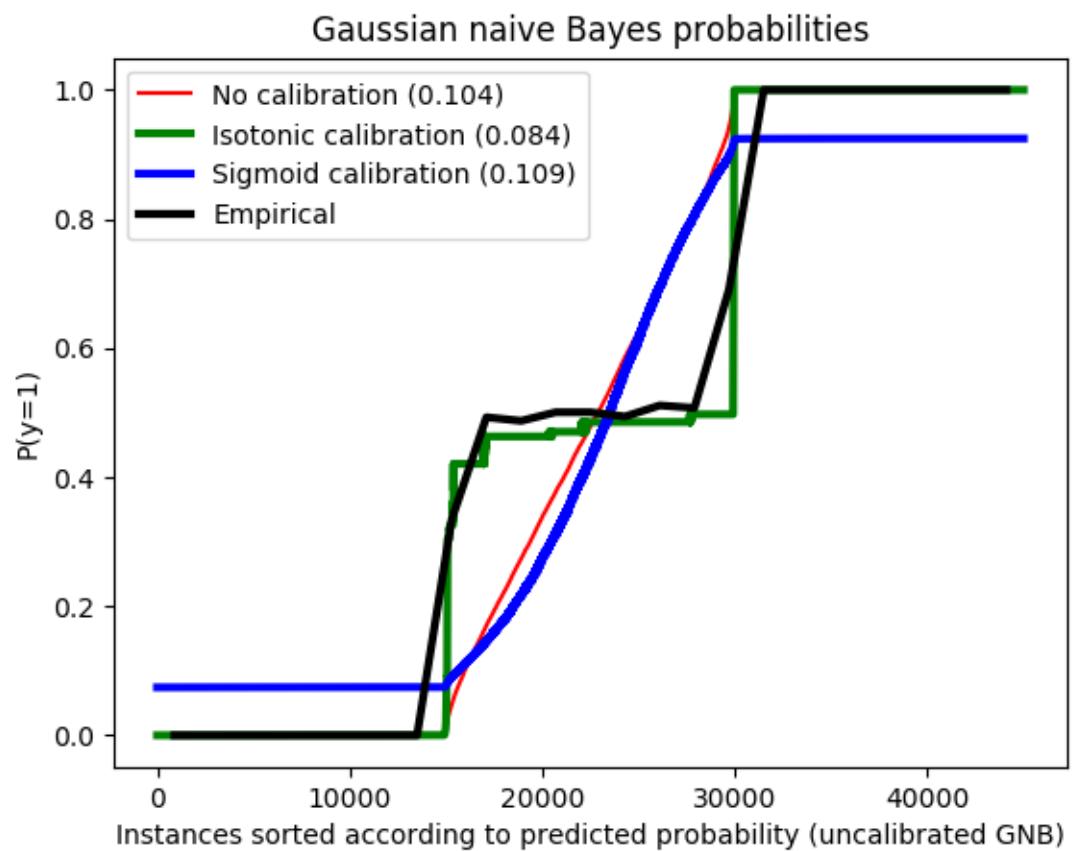

The following image shows on the data above the estimated probability using a Gaussian naive Bayes classifier without calibration, with a sigmoid calibration and with a non-parametric isotonic calibration. One can observe that the non-parametric model provides the most accurate probability estimates for samples in the middle, i.e., 0.5.

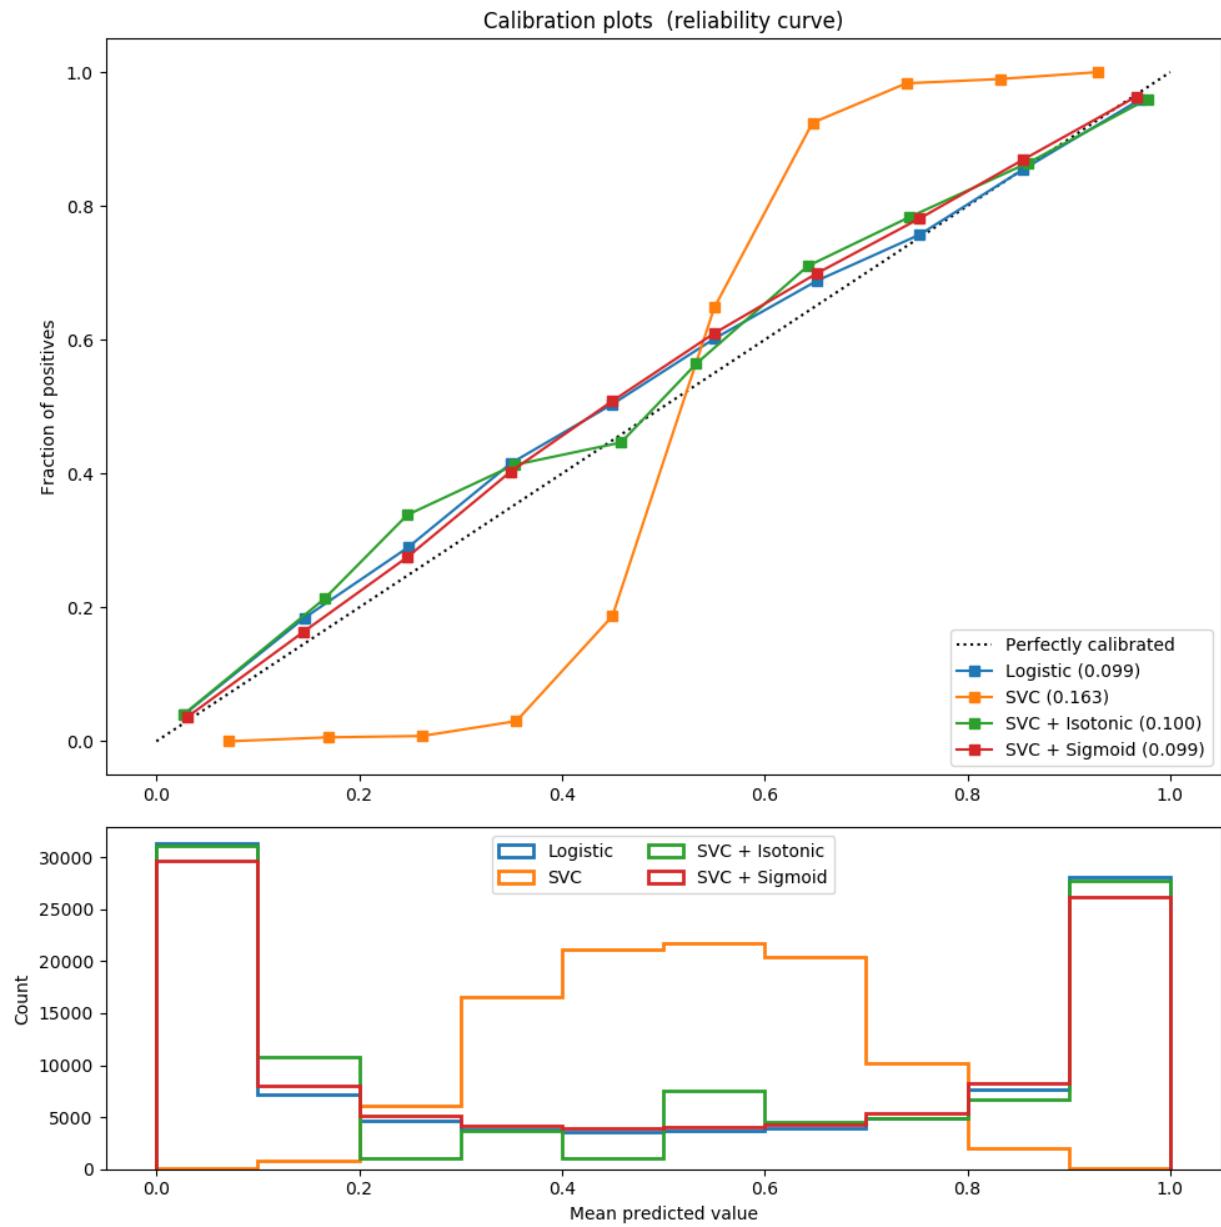

The following experiment is performed on an artificial dataset for binary classification with 100.000 samples (1.000 of them are used for model fitting) with 20 features. Of the 20 features, only 2 are informative and 10 are redundant. The figure shows the estimated probabilities obtained with logistic regression, a linear support-vector classifier (SVC), and linear SVC with both isotonic calibration and sigmoid calibration. The calibration performance is evaluated with Brier score *brier\_score\_loss*, reported in the legend (the smaller the better).

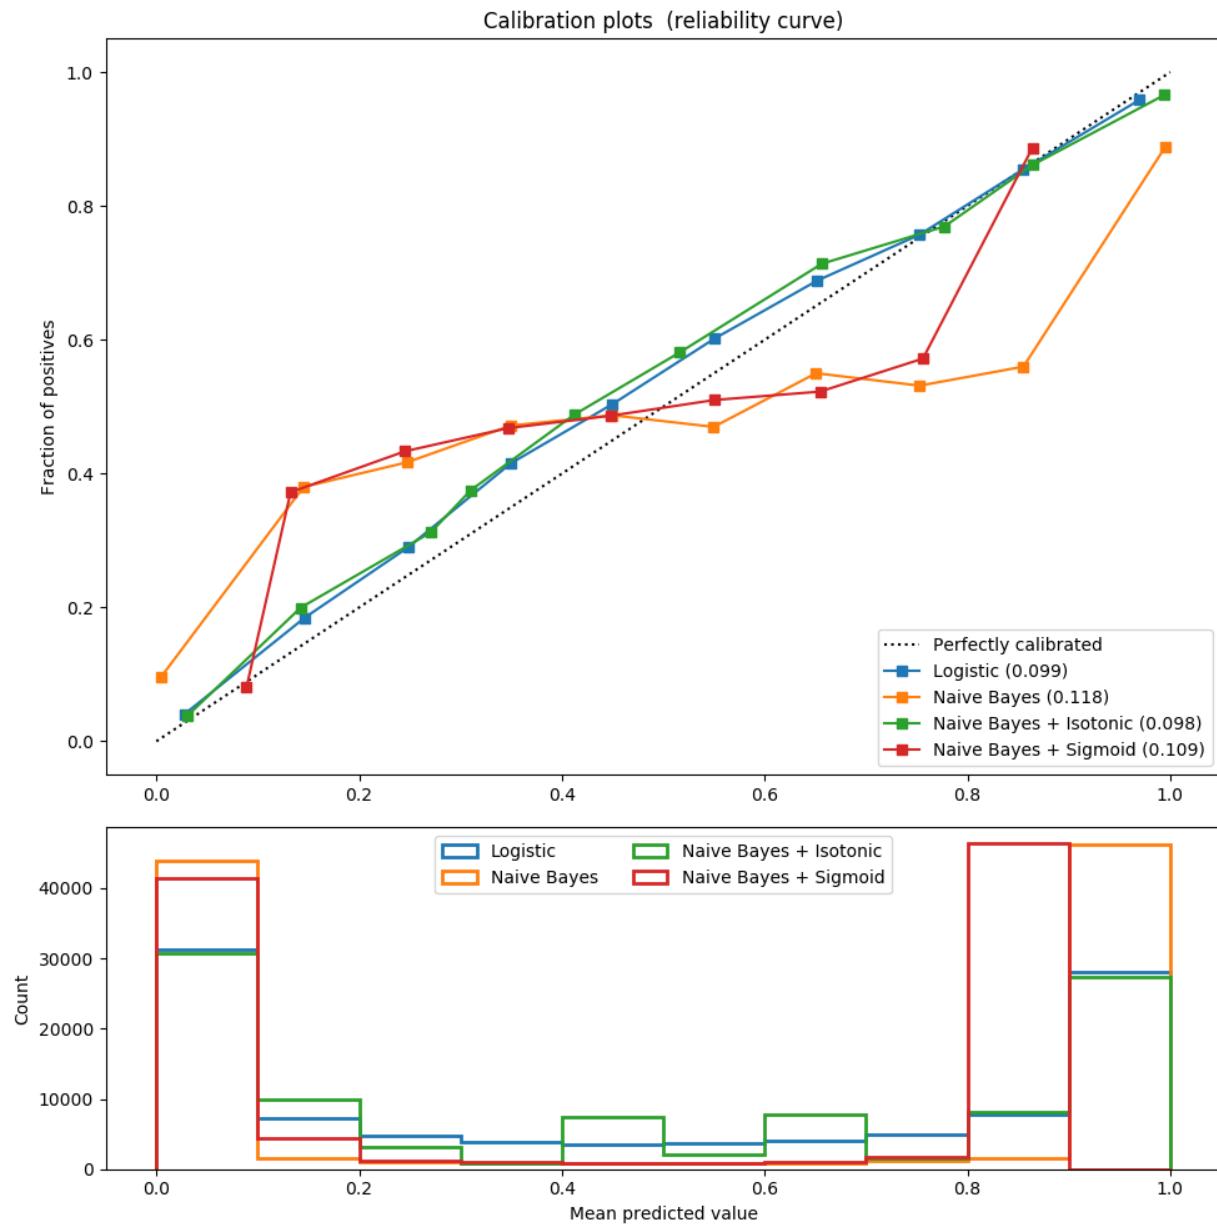

One can observe here that logistic regression is well calibrated as its curve is nearly diagonal. Linear SVC’s calibration curve or reliability diagram has a sigmoid curve, which is typical for an under-confident classifier. In the case of LinearSVC, this is caused by the margin property of the hinge loss, which lets the model focus on hard samples that are close to the decision boundary (the support vectors). Both kinds of calibration can fix this issue and yield nearly identical results. The next figure shows the calibration curve of Gaussian naive Bayes on the same data, with both kinds of calibration and also without calibration.

One can see that Gaussian naive Bayes performs very badly but does so in an other way than linear SVC: While linear SVC exhibited a sigmoid calibration curve, Gaussian naive Bayes’ calibration curve has a transposed-sigmoid shape. This is typical for an over-confident classifier. In this case, the classifier’s overconfidence is caused by the redundant features which violate the naive Bayes assumption of feature-independence.

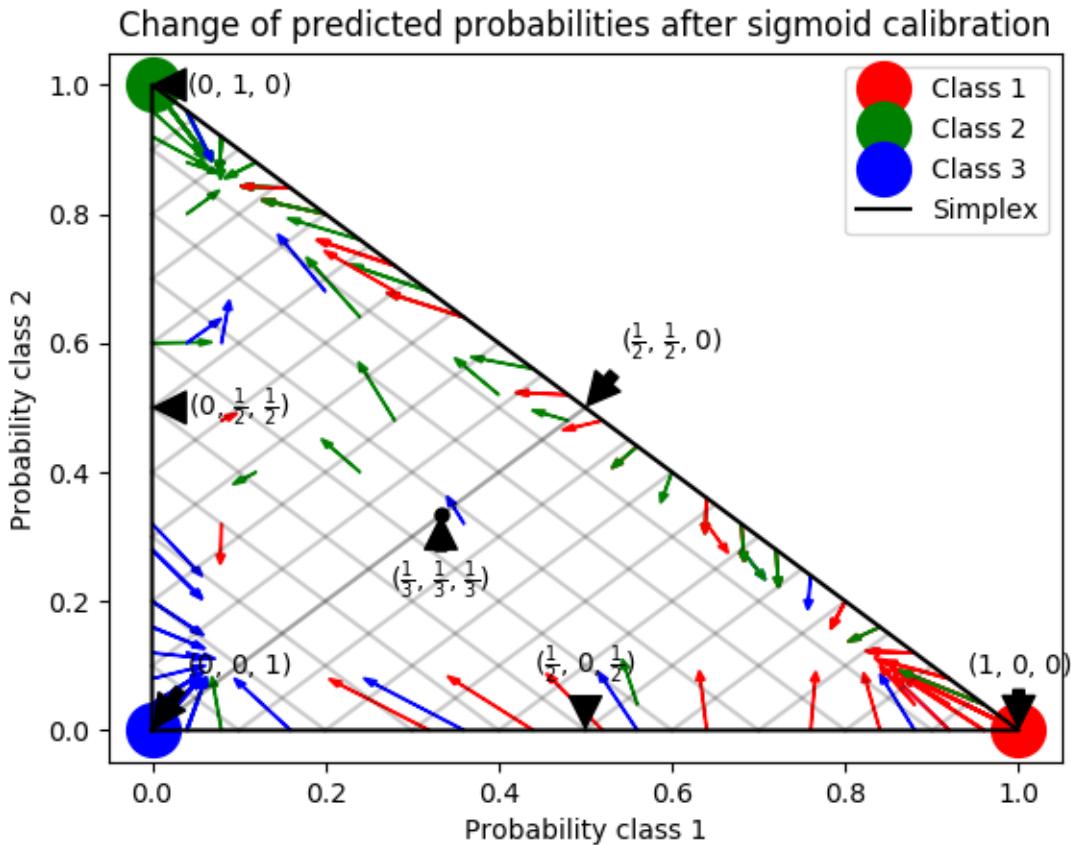

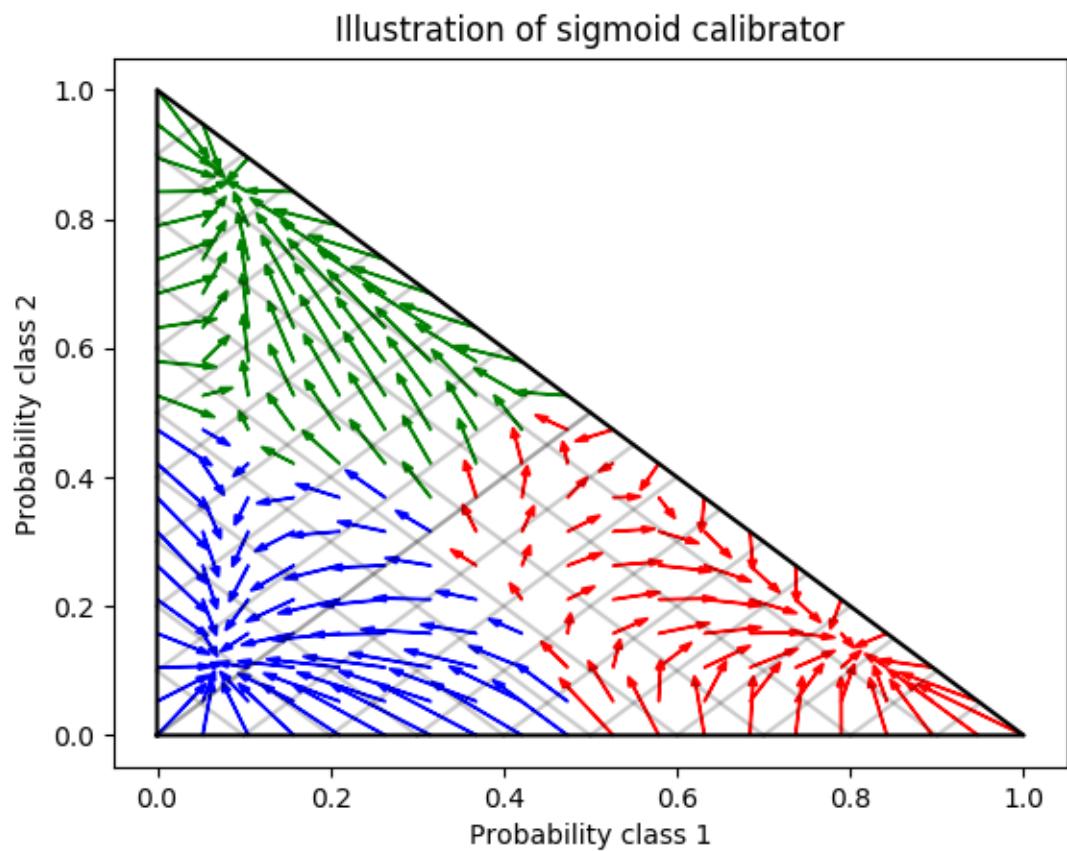

Calibration of the probabilities of Gaussian naive Bayes with isotonic regression can fix this issue as can be seen from the nearly diagonal calibration curve. Sigmoid calibration also improves the brier score slightly, albeit not as strongly as the non-parametric isotonic calibration. This is an intrinsic limitation of sigmoid calibration, whose parametric form assumes a sigmoid rather than a transposed-sigmoid curve. The non-parametric isotonic calibration model, however, makes no such strong assumptions and can deal with either shape, provided that there is sufficient calibration data. In general, sigmoid calibration is preferable in cases where the calibration curve is sigmoid and where there is limited calibration data, while isotonic calibration is preferable for non-sigmoid calibration curves and in situations where large amounts of data are available for calibration.

`CalibratedClassifierCV` can also deal with classification tasks that involve more than two classes if the base estimator can do so. In this case, the classifier is calibrated first for each class separately in an one-vs-rest fashion. When predicting probabilities for unseen data, the calibrated probabilities for each class are predicted separately. As those probabilities do not necessarily sum to one, a postprocessing is performed to normalize them.

The next image illustrates how sigmoid calibration changes predicted probabilities for a 3-class classification problem. Illustrated is the standard 2-simplex, where the three corners correspond to the three classes. Arrows point from the probability vectors predicted by an uncalibrated classifier to the probability vectors predicted by the same classifier after sigmoid calibration on a hold-out validation set. Colors indicate the true class of an instance (red: class 1, green: class 2, blue: class 3).

The base classifier is a random forest classifier with 25 base estimators (trees). If this classifier is trained on all 800 training datapoints, it is overly confident in its predictions and thus incurs a large log-loss. Calibrating an identical classifier, which was trained on 600 datapoints, with method='sigmoid' on the remaining 200 datapoints reduces the confidence of the predictions, i.e., moves the probability vectors from the edges of the simplex towards the center:

This calibration results in a lower log-loss. Note that an alternative would have been to increase the number of base estimators which would have resulted in a similar decrease in log-loss.

### 3.1.17 Neural network models (supervised)

**Warning:** This implementation is not intended for large-scale applications. In particular, scikit-learn offers no GPU support. For much faster, GPU-based implementations, as well as frameworks offering much more flexibility to build deep learning architectures, see [Related Projects](#).

#### Multi-layer Perceptron

**Multi-layer Perceptron (MLP)** is a supervised learning algorithm that learns a function  $f(\cdot) : R^m \rightarrow R^o$  by training on a dataset, where  $m$  is the number of dimensions for input and  $o$  is the number of dimensions for output. Given a set of features  $X = x_1, x_2, \dots, x_m$  and a target  $y$ , it can learn a non-linear function approximator for either classification or regression. It is different from logistic regression, in that between the input and the output layer, there can be one or more non-linear layers, called hidden layers. Figure 1 shows a one hidden layer MLP with scalar output.

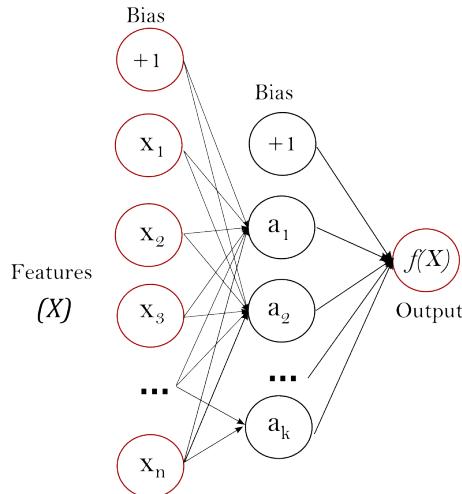

Fig. 3.2: **Figure 1 : One hidden layer MLP.**

The leftmost layer, known as the input layer, consists of a set of neurons  $\{x_i | x_1, x_2, \dots, x_m\}$  representing the input features. Each neuron in the hidden layer transforms the values from the previous layer with a weighted linear summation  $w_1x_1 + w_2x_2 + \dots + w_mx_m$ , followed by a non-linear activation function  $g(\cdot) : R \rightarrow R$  - like the hyperbolic tan function. The output layer receives the values from the last hidden layer and transforms them into output values.

The module contains the public attributes `coefs_` and `intercepts_`. `coefs_` is a list of weight matrices, where weight matrix at index  $i$  represents the weights between layer  $i$  and layer  $i+1$ . `intercepts_` is a list of bias vectors, where the vector at index  $i$  represents the bias values added to layer  $i+1$ .

The advantages of Multi-layer Perceptron are:

- Capability to learn non-linear models.
- Capability to learn models in real-time (on-line learning) using `partial_fit`.

The disadvantages of Multi-layer Perceptron (MLP) include:

- MLP with hidden layers have a non-convex loss function where there exists more than one local minimum. Therefore different random weight initializations can lead to different validation accuracy.
- MLP requires tuning a number of hyperparameters such as the number of hidden neurons, layers, and iterations.
- MLP is sensitive to feature scaling.

Please see [Tips on Practical Use](#) section that addresses some of these disadvantages.

## Classification

Class `MLPClassifier` implements a multi-layer perceptron (MLP) algorithm that trains using Backpropagation.

MLP trains on two arrays: array X of size (n\_samples, n\_features), which holds the training samples represented as floating point feature vectors; and array y of size (n\_samples,), which holds the target values (class labels) for the training samples:

```
>>> from sklearn.neural_network import MLPClassifier
>>> X = [[0., 0.], [1., 1.]]
>>> y = [0, 1]
>>> clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
...                      hidden_layer_sizes=(5, 2), random_state=1)
...
>>> clf.fit(X, y)
MLPClassifier(activation='relu', alpha=1e-05, batch_size='auto',
              beta_1=0.9, beta_2=0.999, early_stopping=False,
              epsilon=1e-08, hidden_layer_sizes=(5, 2), learning_rate='constant',
              learning_rate_init=0.001, max_iter=200, momentum=0.9,
              nesterovs_momentum=True, power_t=0.5, random_state=1, shuffle=True,
              solver='lbfgs', tol=0.0001, validation_fraction=0.1, verbose=False,
              warm_start=False)
```

After fitting (training), the model can predict labels for new samples:

```
>>> clf.predict([[2., 2.], [-1., -2.]])
array([1, 0])
```

MLP can fit a non-linear model to the training data. `clf.coefs_` contains the weight matrices that constitute the model parameters:

```
>>> [coef.shape for coef in clf.coefs_]
[(2, 5), (5, 2), (2, 1)]
```

Currently, `MLPClassifier` supports only the Cross-Entropy loss function, which allows probability estimates by running the `predict_proba` method.

MLP trains using Backpropagation. More precisely, it trains using some form of gradient descent and the gradients are calculated using Backpropagation. For classification, it minimizes the Cross-Entropy loss function, giving a vector of probability estimates  $P(y|x)$  per sample  $x$ :

```
>>> clf.predict_proba([[2., 2.], [1., 2.]])
array([[ 1.967...e-04,    9.998...-01],
       [ 1.967...e-04,    9.998...-01]])
```

`MLPClassifier` supports multi-class classification by applying Softmax as the output function.

Further, the model supports *multi-label classification* in which a sample can belong to more than one class. For each class, the raw output passes through the logistic function. Values larger or equal to 0.5 are rounded to 1, otherwise to 0. For a predicted output of a sample, the indices where the value is 1 represents the assigned classes of that sample:

```
>>> X = [[0., 0.], [1., 1.]]
>>> y = [[0, 1], [1, 1]]
>>> clf = MLPClassifier(solver='lbfgs', alpha=1e-5,
...                      hidden_layer_sizes=(15,), random_state=1)
...
>>> clf.fit(X, y)
MLPClassifier(activation='relu', alpha=1e-05, batch_size='auto',
              beta_1=0.9, beta_2=0.999, early_stopping=False,
              epsilon=1e-08, hidden_layer_sizes=(15,), learning_rate='constant',
              learning_rate_init=0.001, max_iter=200, momentum=0.9,
              nesterovs_momentum=True, power_t=0.5, random_state=1, shuffle=True,
              solver='lbfgs', tol=0.0001, validation_fraction=0.1, verbose=False,
              warm_start=False)
>>> clf.predict([[1., 2.]])
array([[1, 1]])
>>> clf.predict([[0., 0.]])
array([[0, 1]])
```

See the examples below and the doc string of `MLPClassifier.fit` for further information.

### Examples:

- *Compare Stochastic learning strategies for MLPClassifier*
- *Visualization of MLP weights on MNIST*

## Regression

Class `MLPRegressor` implements a multi-layer perceptron (MLP) that trains using backpropagation with no activation function in the output layer, which can also be seen as using the identity function as activation function. Therefore, it uses the square error as the loss function, and the output is a set of continuous values.

`MLPRegressor` also supports multi-output regression, in which a sample can have more than one target.

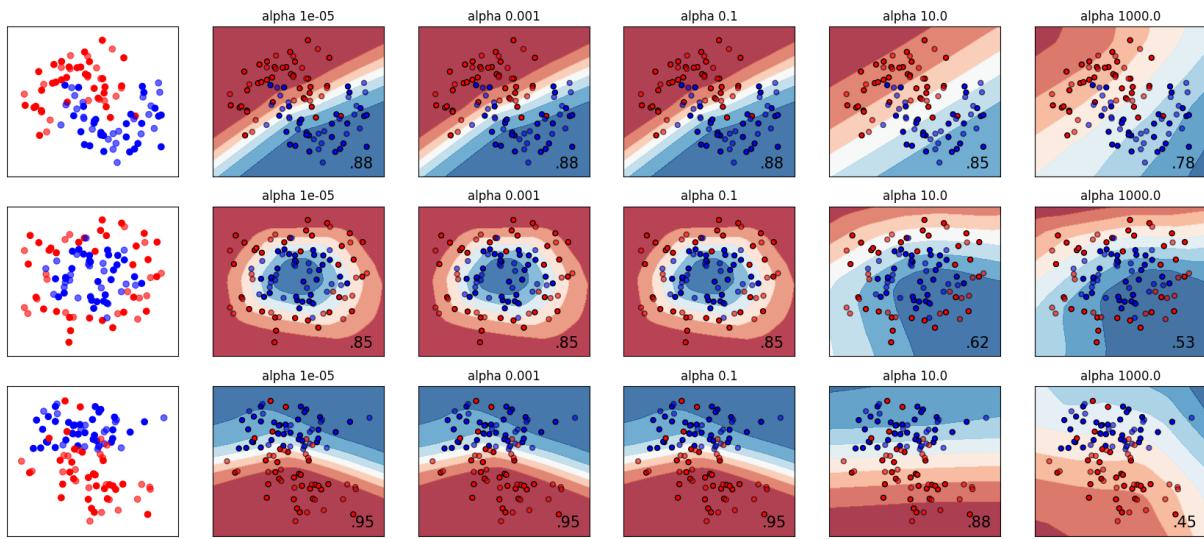

### Regularization

Both `MLPRegressor` and `MLPClassifier` use parameter `alpha` for regularization (L2 regularization) term which helps in avoiding overfitting by penalizing weights with large magnitudes. Following plot displays varying decision function with value of `alpha`.

See the examples below for further information.

### Examples:

- *Varying regularization in Multi-layer Perceptron*

## Algorithms

MLP trains using [Stochastic Gradient Descent](#), [Adam](#), or [L-BFGS](#). Stochastic Gradient Descent (SGD) updates parameters using the gradient of the loss function with respect to a parameter that needs adaptation, i.e.

$$w \leftarrow w - \eta(\alpha \frac{\partial R(w)}{\partial w} + \frac{\partial Loss}{\partial w})$$

where  $\eta$  is the learning rate which controls the step-size in the parameter space search. *Loss* is the loss function used for the network.

More details can be found in the documentation of [SGD](#)

Adam is similar to SGD in a sense that it is a stochastic optimizer, but it can automatically adjust the amount to update parameters based on adaptive estimates of lower-order moments.

With SGD or Adam, training supports online and mini-batch learning.

L-BFGS is a solver that approximates the Hessian matrix which represents the second-order partial derivative of a function. Further it approximates the inverse of the Hessian matrix to perform parameter updates. The implementation uses the Scipy version of [L-BFGS](#).

If the selected solver is ‘L-BFGS’, training does not support online nor mini-batch learning.

## Complexity

Suppose there are  $n$  training samples,  $m$  features,  $k$  hidden layers, each containing  $h$  neurons - for simplicity, and  $o$  output neurons. The time complexity of backpropagation is  $O(n \cdot m \cdot h^k \cdot o \cdot i)$ , where  $i$  is the number of iterations. Since backpropagation has a high time complexity, it is advisable to start with smaller number of hidden neurons and few hidden layers for training.

## Mathematical formulation

Given a set of training examples  $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$  where  $x_i \in \mathbf{R}^n$  and  $y_i \in \{0, 1\}$ , a one hidden layer one hidden neuron MLP learns the function  $f(x) = W_2 g(W_1^T x + b_1) + b_2$  where  $W_1 \in \mathbf{R}^m$  and  $W_2, b_1, b_2 \in \mathbf{R}$  are model parameters.  $W_1, W_2$  represent the weights of the input layer and hidden layer, respectively; and  $b_1, b_2$  represent the bias added to the hidden layer and the output layer, respectively.  $g(\cdot) : \mathbf{R} \rightarrow \mathbf{R}$  is the activation function, set by default as the hyperbolic tan. It is given as,

$$g(z) = \frac{e^z - e^{-z}}{e^z + e^{-z}}$$

For binary classification,  $f(x)$  passes through the logistic function  $g(z) = 1/(1+e^{-z})$  to obtain output values between zero and one. A threshold, set to 0.5, would assign samples of outputs larger or equal 0.5 to the positive class, and the rest to the negative class.

If there are more than two classes,  $f(x)$  itself would be a vector of size (n\_classes,). Instead of passing through logistic function, it passes through the softmax function, which is written as,

$$\text{softmax}(z)_i = \frac{\exp(z_i)}{\sum_{l=1}^k \exp(z_l)}$$

where  $z_i$  represents the  $i$  th element of the input to softmax, which corresponds to class  $i$ , and  $K$  is the number of classes. The result is a vector containing the probabilities that sample  $x$  belong to each class. The output is the class with the highest probability.

In regression, the output remains as  $f(x)$ ; therefore, output activation function is just the identity function.

MLP uses different loss functions depending on the problem type. The loss function for classification is Cross-Entropy, which in binary case is given as,

$$\text{Loss}(\hat{y}, y, W) = -y \ln \hat{y} - (1 - y) \ln (1 - \hat{y}) + \alpha \|W\|_2^2$$

where  $\alpha \|W\|_2^2$  is an L2-regularization term (aka penalty) that penalizes complex models; and  $\alpha > 0$  is a non-negative hyperparameter that controls the magnitude of the penalty.

For regression, MLP uses the Square Error loss function; written as,

$$\text{Loss}(\hat{y}, y, W) = \frac{1}{2} \|\hat{y} - y\|_2^2 + \frac{\alpha}{2} \|W\|_2^2$$

Starting from initial random weights, multi-layer perceptron (MLP) minimizes the loss function by repeatedly updating these weights. After computing the loss, a backward pass propagates it from the output layer to the previous layers, providing each weight parameter with an update value meant to decrease the loss.

In gradient descent, the gradient  $\nabla \text{Loss}_W$  of the loss with respect to the weights is computed and deducted from  $W$ . More formally, this is expressed as,

$$W^{i+1} = W^i - \epsilon \nabla \text{Loss}_W^i$$

where  $i$  is the iteration step, and  $\epsilon$  is the learning rate with a value larger than 0.

The algorithm stops when it reaches a preset maximum number of iterations; or when the improvement in loss is below a certain, small number.

## Tips on Practical Use

- Multi-layer Perceptron is sensitive to feature scaling, so it is highly recommended to scale your data. For example, scale each attribute on the input vector X to [0, 1] or [-1, +1], or standardize it to have mean 0 and variance 1. Note that you must apply the *same* scaling to the test set for meaningful results. You can use StandardScaler for standardization.

```
>>> from sklearn.preprocessing import StandardScaler
>>> scaler = StandardScaler()
>>> # Don't cheat - fit only on training data
>>> scaler.fit(X_train)
>>> X_train = scaler.transform(X_train)
>>> # apply same transformation to test data
>>> X_test = scaler.transform(X_test)
```

An alternative and recommended approach is to use `StandardScaler` in a Pipeline

- Finding a reasonable regularization parameter  $\alpha$  is best done using `GridSearchCV`, usually in the range  $10^{-4} \dots 10^{-1}$ .
- Empirically, we observed that *L-BFGS* converges faster and with better solutions on small datasets. For relatively large datasets, however, *Adam* is very robust. It usually converges quickly and gives pretty good performance. *SGD* with momentum or nesterov's momentum, on the other hand, can perform better than those two algorithms if learning rate is correctly tuned.

## More control with `warm_start`

If you want more control over stopping criteria or learning rate in SGD, or want to do additional monitoring, using `warm_start=True` and `max_iter=1` and iterating yourself can be helpful:

```
>>> X = [[0., 0.], [1., 1.]]
>>> y = [0, 1]
>>> clf = MLPClassifier(hidden_layer_sizes=(15,), random_state=1, max_iter=1, warm_
>>> start=True)
>>> for i in range(10):
...     clf.fit(X, y)
...     # additional monitoring / inspection
MLPClassifier(...)
```

## 3.2 Unsupervised learning

### 3.2.1 Gaussian mixture models

`sklearn.mixture` is a package which enables one to learn Gaussian Mixture Models (diagonal, spherical, tied and full covariance matrices supported), sample them, and estimate them from data. Facilities to help determine the appropriate number of components are also provided.

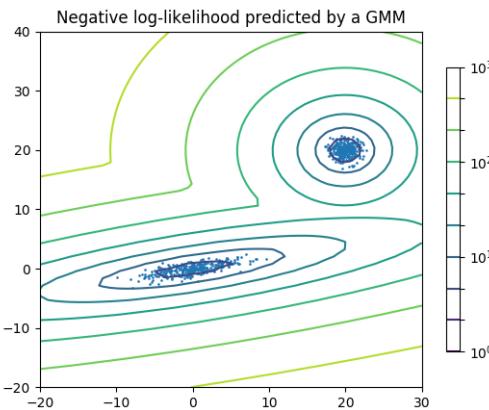

Fig. 3.3: **Two-component Gaussian mixture model:** *data points, and equi-probability surfaces of the model.*

A Gaussian mixture model is a probabilistic model that assumes all the data points are generated from a mixture of a finite number of Gaussian distributions with unknown parameters. One can think of mixture models as generalizing k-means clustering to incorporate information about the covariance structure of the data as well as the centers of the latent Gaussians.

Scikit-learn implements different classes to estimate Gaussian mixture models, that correspond to different estimation strategies, detailed below.

## Gaussian Mixture

The `GaussianMixture` object implements the *expectation-maximization* (EM) algorithm for fitting mixture-of-Gaussian models. It can also draw confidence ellipsoids for multivariate models, and compute the Bayesian Information Criterion to assess the number of clusters in the data. A `GaussianMixture.fit` method is provided that learns a Gaussian Mixture Model from train data. Given test data, it can assign to each sample the Gaussian it mostly probably belong to using the `GaussianMixture.predict` method.

The `GaussianMixture` comes with different options to constrain the covariance of the difference classes estimated: spherical, diagonal, tied or full covariance.

### Examples:

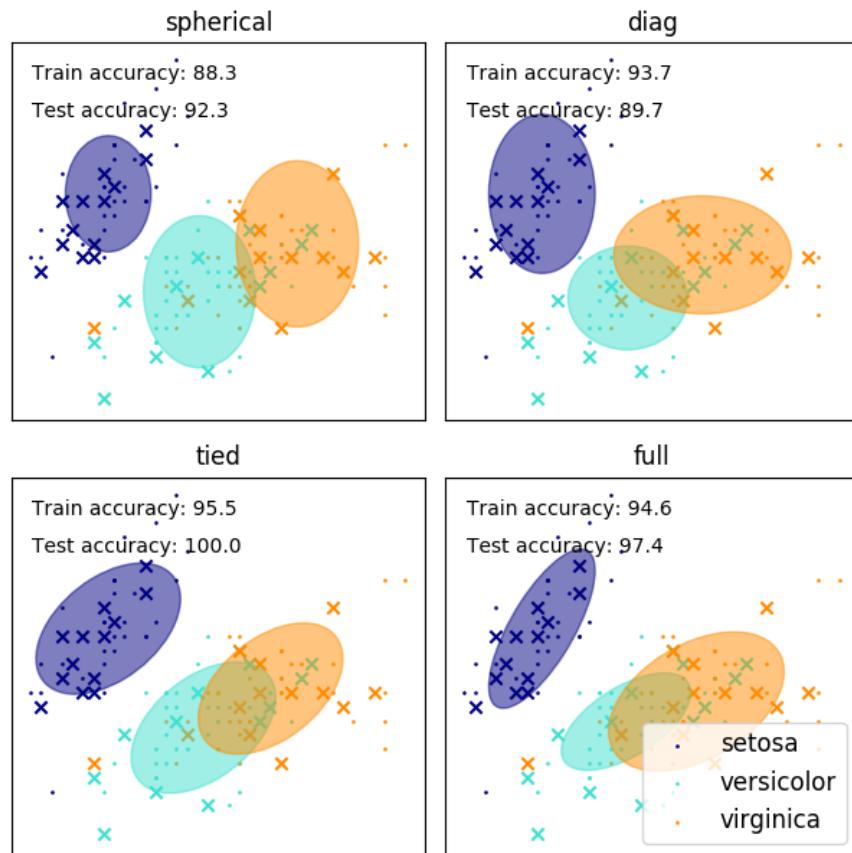

- See [GMM covariances](#) for an example of using the Gaussian mixture as clustering on the iris dataset.
- See [Density Estimation for a Gaussian mixture](#) for an example on plotting the density estimation.

## Pros and cons of class `GaussianMixture`

### Pros

**Speed** It is the fastest algorithm for learning mixture models

**Agnostic** As this algorithm maximizes only the likelihood, it will not bias the means towards zero, or bias the cluster sizes to have specific structures that might or might not apply.

## Cons

**Singularities** When one has insufficiently many points per mixture, estimating the covariance matrices becomes difficult, and the algorithm is known to diverge and find solutions with infinite likelihood unless one regularizes the covariances artificially.

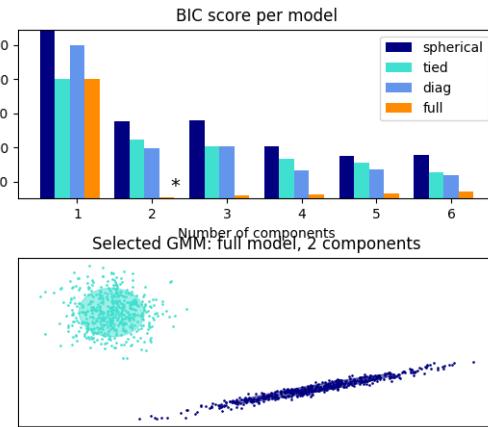

**Number of components** This algorithm will always use all the components it has access to, needing held-out data or information theoretical criteria to decide how many components to use in the absence of external cues.

## Selecting the number of components in a classical Gaussian Mixture Model

The BIC criterion can be used to select the number of components in a Gaussian Mixture in an efficient way. In theory, it recovers the true number of components only in the asymptotic regime (i.e. if much data is available and assuming that the data was actually generated i.i.d. from a mixture of Gaussian distribution). Note that using a [Variational Bayesian Gaussian mixture](#) avoids the specification of the number of components for a Gaussian mixture model.

### Examples:

- See [Gaussian Mixture Model Selection](#) for an example of model selection performed with classical Gaussian mixture.

## Estimation algorithm Expectation-maximization

The main difficulty in learning Gaussian mixture models from unlabeled data is that it is one usually doesn't know which points came from which latent component (if one has access to this information it gets very easy to fit a separate Gaussian distribution to each set of points). [Expectation-maximization](#) is a well-founded statistical algorithm to get around this problem by an iterative process. First one assumes random components (randomly centered on data points, learned from k-means, or even just normally distributed around the origin) and computes for each point a probability of being generated by each component of the model. Then, one tweaks the parameters to maximize the likelihood of the data given those assignments. Repeating this process is guaranteed to always converge to a local optimum.

## Variational Bayesian Gaussian Mixture

The [\*BayesianGaussianMixture\*](#) object implements a variant of the Gaussian mixture model with variational inference algorithms. The API is similar as the one defined by [\*GaussianMixture\*](#).

### Estimation algorithm: variational inference

Variational inference is an extension of expectation-maximization that maximizes a lower bound on model evidence (including priors) instead of data likelihood. The principle behind variational methods is the same as expectation-maximization (that is both are iterative algorithms that alternate between finding the probabilities for each point to be generated by each mixture and fitting the mixture to these assigned points), but variational methods add regularization by integrating information from prior distributions. This avoids the singularities often found in expectation-maximization solutions but introduces some subtle biases to the model. Inference is often notably slower, but not usually as much so as to render usage unpractical.

Due to its Bayesian nature, the variational algorithm needs more hyper-parameters than expectation-maximization, the most important of these being the concentration parameter `weight_concentration_prior`. Specifying a low value for the concentration prior will make the model put most of the weight on few components set the remaining components weights very close to zero. High values of the concentration prior will allow a larger number of components to be active in the mixture.

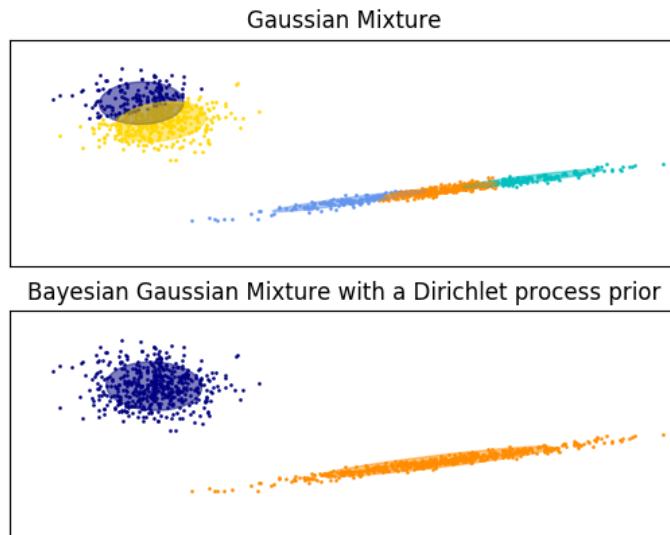

The parameters implementation of the [\*BayesianGaussianMixture\*](#) class proposes two types of prior for the weights distribution: a finite mixture model with Dirichlet distribution and an infinite mixture model with the Dirichlet Process. In practice Dirichlet Process inference algorithm is approximated and uses a truncated distribution with a fixed maximum number of components (called the Stick-breaking representation). The number of components actually used almost always depends on the data.

The next figure compares the results obtained for the different type of the weight concentration prior (parameter `weight_concentration_prior_type`) for different values of `weight_concentration_prior`. Here, we can see the value of the `weight_concentration_prior` parameter has a strong impact on the effective number of active components obtained. We can also notice that large values for the concentration weight prior lead to more uniform weights when the type of prior is ‘dirichlet\_distribution’ while this is not necessarily the case for the ‘dirichlet\_process’ type (used by default).

The examples below compare Gaussian mixture models with a fixed number of components, to the variational Gaus-

sian mixture models with a Dirichlet process prior. Here, a classical Gaussian mixture is fitted with 5 components on a dataset composed of 2 clusters. We can see that the variational Gaussian mixture with a Dirichlet process prior is able to limit itself to only 2 components whereas the Gaussian mixture fits the data with a fixed number of components that has to be set a priori by the user. In this case the user has selected `n_components=5` which does not match the true generative distribution of this toy dataset. Note that with very little observations, the variational Gaussian mixture models with a Dirichlet process prior can take a conservative stand, and fit only one component.

On the following figure we are fitting a dataset not well-depicted by a Gaussian mixture. Adjusting the `weight_concentration_prior`, parameter of the class: `BayesianGaussianMixture` controls the number of components used to fit this data. We also present on the last two plots a random sampling generated from the two resulting mixtures.

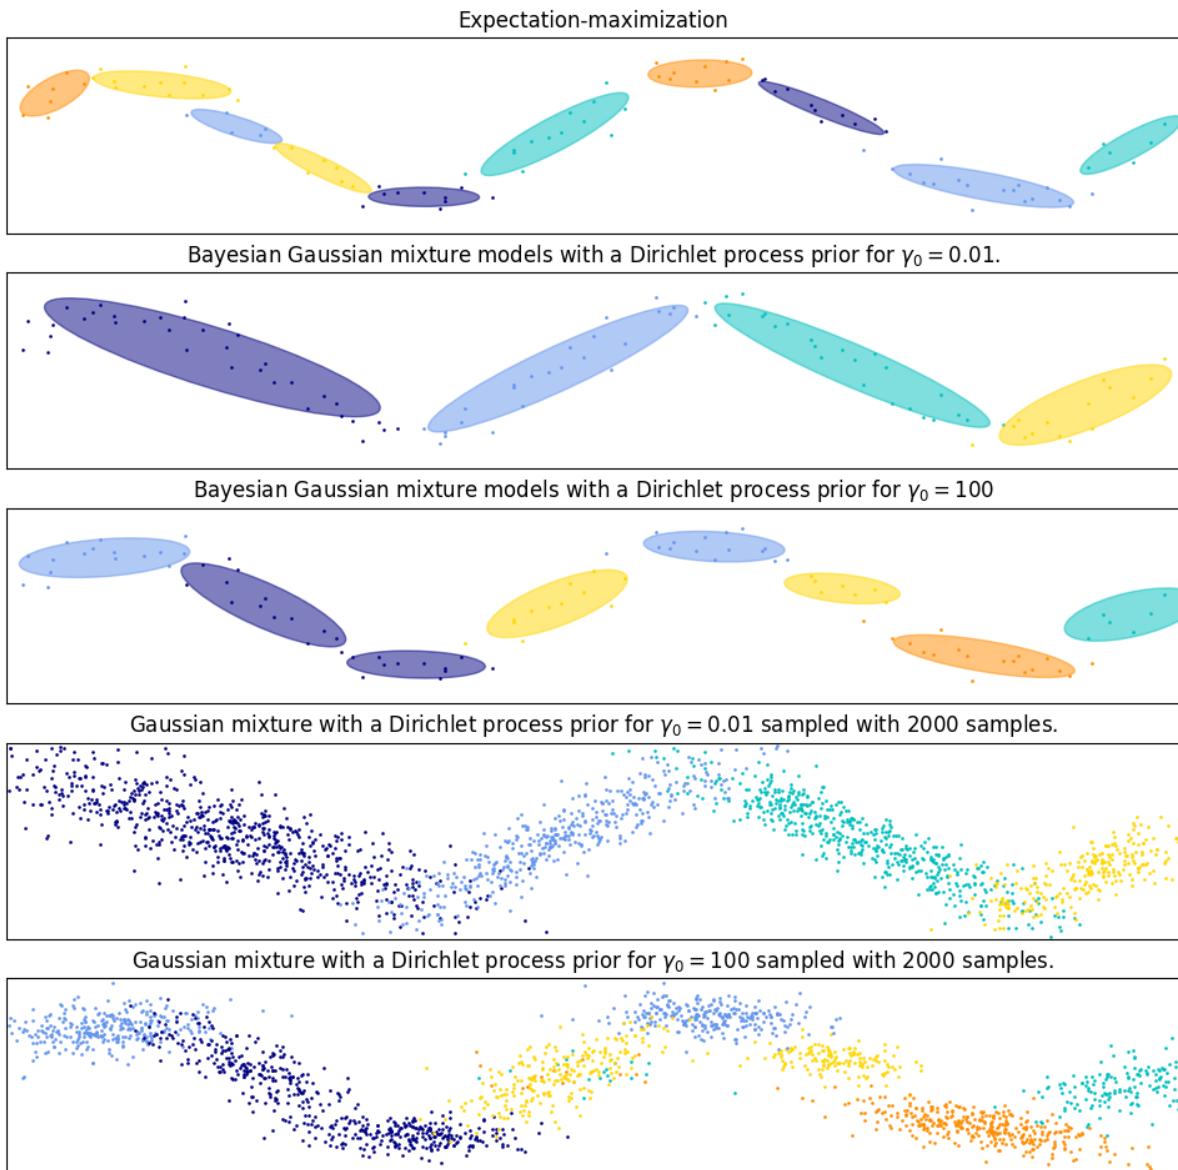

#### Examples:

- See [Gaussian Mixture Model Ellipsoids](#) for an example on plotting the confidence ellipsoids for both `GaussianMixture` and `BayesianGaussianMixture`.
- [Gaussian Mixture Model Sine Curve](#) shows using `GaussianMixture` and `BayesianGaussianMixture` to fit a sine wave.
- See [Concentration Prior Type Analysis of Variation Bayesian Gaussian Mixture](#) for an example plotting the confidence ellipsoids for the `BayesianGaussianMixture` with different `weight_concentration_prior_type` for different values of the parameter `weight_concentration_prior`.

#### Pros and cons of variational inference with `BayesianGaussianMixture`

##### Pros

**Automatic selection** when `weight_concentration_prior` is small enough and `n_components` is larger than what is found necessary by the model, the Variational Bayesian

mixture model has a natural tendency to set some mixture weights values close to zero. This makes it possible to let the model choose a suitable number of effective components automatically. Only an upper bound of this number needs to be provided. Note however that the “ideal” number of active components is very application specific and is typically ill-defined in a data exploration setting.

**Less sensitivity to the number of parameters** unlike finite models, which will almost always use all components as much as they can, and hence will produce wildly different solutions for different numbers of components, the variational inference with a Dirichlet process prior (`weight_concentration_prior_type='dirichlet_process'`) won’t change much with changes to the parameters, leading to more stability and less tuning.

**Regularization** due to the incorporation of prior information, variational solutions have less pathological special cases than expectation-maximization solutions.

## Cons

**Speed** the extra parametrization necessary for variational inference make inference slower, although not by much.

**Hyperparameters** this algorithm needs an extra hyperparameter that might need experimental tuning via cross-validation.

**Bias** there are many implicit biases in the inference algorithms (and also in the Dirichlet process if used), and whenever there is a mismatch between these biases and the data it might be possible to fit better models using a finite mixture.

## The Dirichlet Process

Here we describe variational inference algorithms on Dirichlet process mixture. The Dirichlet process is a prior probability distribution on *clusterings with an infinite, unbounded, number of partitions*. Variational techniques let us incorporate this prior structure on Gaussian mixture models at almost no penalty in inference time, comparing with a finite Gaussian mixture model.

An important question is how can the Dirichlet process use an infinite, unbounded number of clusters and still be consistent. While a full explanation doesn’t fit this manual, one can think of its [stick breaking process](#) analogy to help understanding it. The stick breaking process is a generative story for the Dirichlet process. We start with a unit-length stick and in each step we break off a portion of the remaining stick. Each time, we associate the length of the piece of the stick to the proportion of points that falls into a group of the mixture. At the end, to represent the infinite mixture, we associate the last remaining piece of the stick to the proportion of points that don’t fall into all the other groups. The length of each piece is random variable with probability proportional to the concentration parameter. Smaller value of the concentration will divide the unit-length into larger pieces of the stick (defining more concentrated distribution). Larger concentration values will create smaller pieces of the stick (increasing the number of components with non zero weights).

Variational inference techniques for the Dirichlet process still work with a finite approximation to this infinite mixture model, but instead of having to specify a priori how many components one wants to use, one just specifies the concentration parameter and an upper bound on the number of mixture components (this upper bound, assuming it is higher than the “true” number of components, affects only algorithmic complexity, not the actual number of components used).

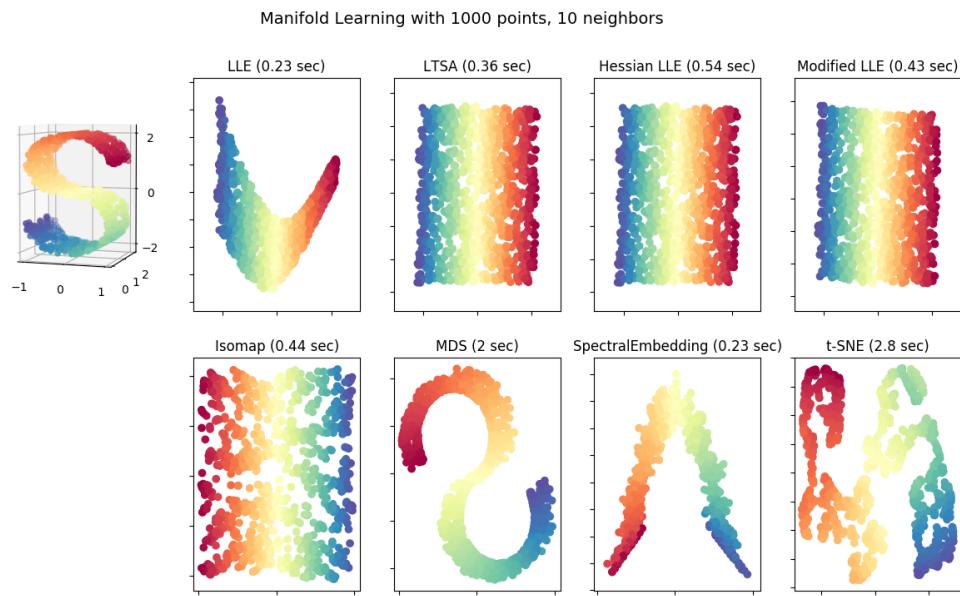

### 3.2.2 Manifold learning

Look for the bare necessities

The simple bare necessities

Forget about your worries and your strife  
 I mean the bare necessities  
 Old Mother Nature's recipes  
 That bring the bare necessities of life

– Baloo's song [The Jungle Book]

Manifold learning is an approach to non-linear dimensionality reduction. Algorithms for this task are based on the idea that the dimensionality of many data sets is only artificially high.

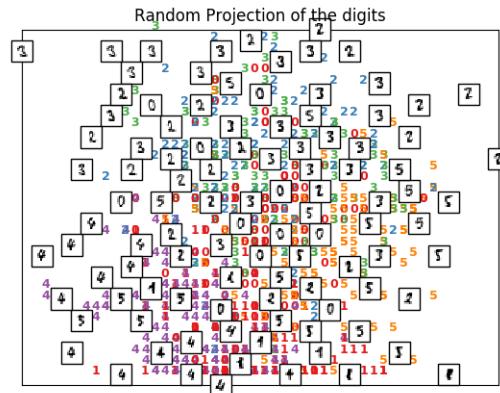

## Introduction

High-dimensional datasets can be very difficult to visualize. While data in two or three dimensions can be plotted to show the inherent structure of the data, equivalent high-dimensional plots are much less intuitive. To aid visualization of the structure of a dataset, the dimension must be reduced in some way.

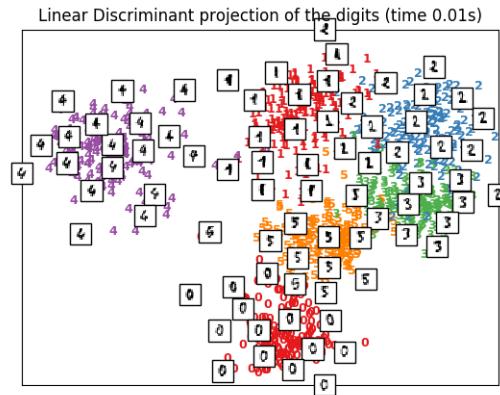

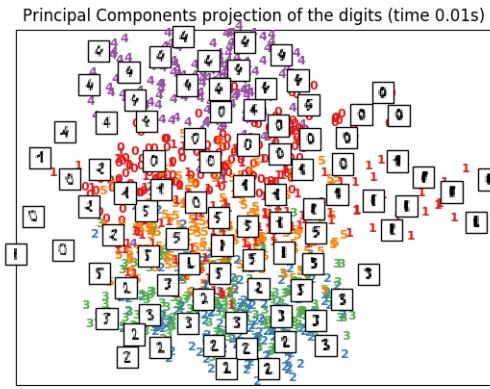

The simplest way to accomplish this dimensionality reduction is by taking a random projection of the data. Though this allows some degree of visualization of the data structure, the randomness of the choice leaves much to be desired. In a random projection, it is likely that the more interesting structure within the data will be lost.

A selection from the 64-dimensional digits dataset

0	1	2	3	4	5	0	1	2	3	4	5	0	5
5	5	0	6	4	1	3	5	1	0	0	2	2	0
4	4	1	5	0	5	2	4	0	0	1	3	1	3
3	4	4	6	5	7	4	5	2	2	2	1	4	3
2	3	4	5	5	1	2	1	3	4	3	1	3	3
0	4	3	5	4	0	0	2	2	0	4	1	3	3
1	5	0	5	2	2	0	0	1	2	1	4	3	4
0	5	2	4	5	4	1	2	1	5	4	4	0	0
5	0	2	5	4	1	0	4	2	3	4	5	0	0
5	2	2	0	0	2	2	0	4	2	3	3	4	6
5	2	2	0	0	4	3	2	1	4	3	3	1	6
3	4	5	4	2	2	0	4	3	3	3	4	4	5
3	4	5	4	2	2	0	4	3	3	3	4	4	5
0	1	3	4	5	0	1	2	3	4	5	0	1	3
5	1	0	0	1	2	0	1	2	3	3	4	4	5
1	2	0	0	1	3	2	1	4	3	1	4	5	0
1	5	4	4	2	2	1	2	5	6	4	0	0	1
2	3	4	5	0	1	2	3	4	5	0	4	1	3
0	0	1	2	0	1	3	3	3	4	4	5	0	1
0	0	1	2	1	3	4	3	1	4	0	5	3	1
0	4	2	1	5	5	4	0	0	1	2	3	4	5

To address this concern, a number of supervised and unsupervised linear dimensionality reduction frameworks have been designed, such as Principal Component Analysis (PCA), Independent Component Analysis, Linear Discriminant Analysis, and others. These algorithms define specific rubrics to choose an “interesting” linear projection of the data. These methods can be powerful, but often miss important non-linear structure in the data.

Manifold Learning can be thought of as an attempt to generalize linear frameworks like PCA to be sensitive to non-linear structure in data. Though supervised variants exist, the typical manifold learning problem is unsupervised: it learns the high-dimensional structure of the data from the data itself, without the use of predetermined classifications.

### Examples:

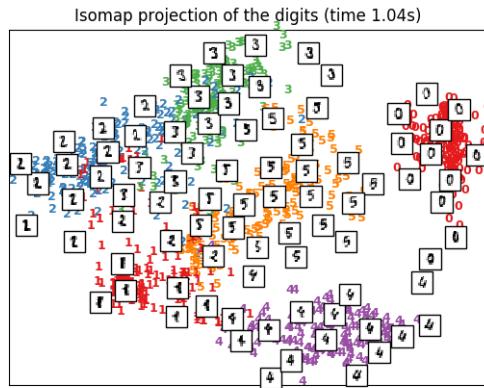

- See [Manifold learning on handwritten digits: Locally Linear Embedding, Isomap...](#) for an example of dimensionality reduction on handwritten digits.
- See [Comparison of Manifold Learning methods](#) for an example of dimensionality reduction on a toy “S-curve” dataset.

The manifold learning implementations available in scikit-learn are summarized below

### Isomap

One of the earliest approaches to manifold learning is the Isomap algorithm, short for Isometric Mapping. Isomap can be viewed as an extension of Multi-dimensional Scaling (MDS) or Kernel PCA. Isomap seeks a lower-dimensional

embedding which maintains geodesic distances between all points. Isomap can be performed with the object [Isomap](#).

## Complexity

The Isomap algorithm comprises three stages:

1. **Nearest neighbor search.** Isomap uses `sklearn.neighbors.BallTree` for efficient neighbor search. The cost is approximately  $O[D \log(k)N \log(N)]$ , for  $k$  nearest neighbors of  $N$  points in  $D$  dimensions.
2. **Shortest-path graph search.** The most efficient known algorithms for this are *Dijkstra's Algorithm*, which is approximately  $O[N^2(k + \log(N))]$ , or the *Floyd-Warshall algorithm*, which is  $O[N^3]$ . The algorithm can be selected by the user with the `path_method` keyword of `Isomap`. If unspecified, the code attempts to choose the best algorithm for the input data.
3. **Partial eigenvalue decomposition.** The embedding is encoded in the eigenvectors corresponding to the  $d$  largest eigenvalues of the  $N \times N$  isomap kernel. For a dense solver, the cost is approximately  $O[dN^2]$ . This cost can often be improved using the ARPACK solver. The eigensolver can be specified by the user with the `path_method` keyword of `Isomap`. If unspecified, the code attempts to choose the best algorithm for the input data.

The overall complexity of Isomap is  $O[D \log(k)N \log(N)] + O[N^2(k + \log(N))] + O[dN^2]$ .

- $N$  : number of training data points
- $D$  : input dimension
- $k$  : number of nearest neighbors
- $d$  : output dimension

## Locally Linear Embedding

Locally linear embedding (LLE) seeks a lower-dimensional projection of the data which preserves distances within local neighborhoods. It can be thought of as a series of local Principal Component Analyses which are globally compared to find the best non-linear embedding.

Locally linear embedding can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`.

## Complexity

The standard LLE algorithm comprises three stages:

1. **Nearest Neighbors Search.** See discussion under Isomap above.
2. **Weight Matrix Construction.**  $O[DNk^3]$ . The construction of the LLE weight matrix involves the solution of a  $k \times k$  linear equation for each of the  $N$  local neighborhoods
3. **Partial Eigenvalue Decomposition.** See discussion under Isomap above.

The overall complexity of standard LLE is  $O[D \log(k)N \log(N)] + O[DNk^3] + O[dN^2]$ .

- $N$  : number of training data points
- $D$  : input dimension
- $k$  : number of nearest neighbors
- $d$  : output dimension

### References:

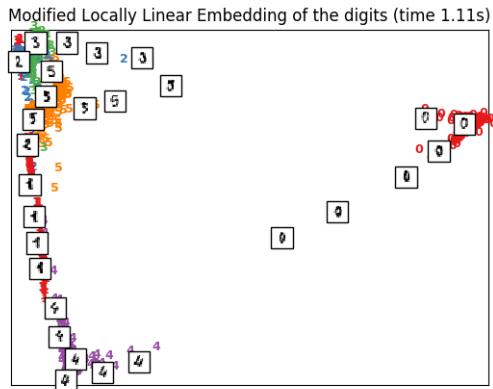

- “Nonlinear dimensionality reduction by locally linear embedding” Roweis, S. & Saul, L. Science 290:2323 (2000)

## Modified Locally Linear Embedding

One well-known issue with LLE is the regularization problem. When the number of neighbors is greater than the number of input dimensions, the matrix defining each local neighborhood is rank-deficient. To address this, standard

LLE applies an arbitrary regularization parameter  $r$ , which is chosen relative to the trace of the local weight matrix. Though it can be shown formally that as  $r \rightarrow 0$ , the solution converges to the desired embedding, there is no guarantee that the optimal solution will be found for  $r > 0$ . This problem manifests itself in embeddings which distort the underlying geometry of the manifold.

One method to address the regularization problem is to use multiple weight vectors in each neighborhood. This is the essence of *modified locally linear embedding* (MLLE). MLLE can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`, with the keyword `method = 'modified'`. It requires `n_neighbors > n_components`.

## Complexity

The MLLE algorithm comprises three stages:

1. **Nearest Neighbors Search.** Same as standard LLE
2. **Weight Matrix Construction.** Approximately  $O[DNk^3] + O[N(k-D)k^2]$ . The first term is exactly equivalent to that of standard LLE. The second term has to do with constructing the weight matrix from multiple weights. In practice, the added cost of constructing the MLLE weight matrix is relatively small compared to the cost of steps 1 and 3.
3. **Partial Eigenvalue Decomposition.** Same as standard LLE

The overall complexity of MLLE is  $O[D \log(k)N \log(N)] + O[DNk^3] + O[N(k-D)k^2] + O[dN^2]$ .

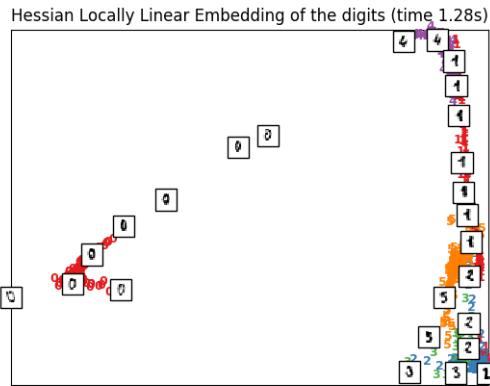

- $N$  : number of training data points
- $D$  : input dimension
- $k$  : number of nearest neighbors
- $d$  : output dimension

## References:

- “MLLE: Modified Locally Linear Embedding Using Multiple Weights” Zhang, Z. & Wang, J.

## Hessian Eigenmapping

Hessian Eigenmapping (also known as Hessian-based LLE: HLLE) is another method of solving the regularization problem of LLE. It revolves around a hessian-based quadratic form at each neighborhood which is used to recover the locally linear structure. Though other implementations note its poor scaling with data size, sklearn implements some algorithmic improvements which make its cost comparable to that of other LLE variants for small output dimension. HLLE can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`, with the keyword method = 'hessian'. It requires `n_neighbors > n_components * (n_components + 3) / 2`.

## Complexity

The HLLE algorithm comprises three stages:

1. **Nearest Neighbors Search.** Same as standard LLE
2. **Weight Matrix Construction.** Approximately  $O[DNk^3] + O[Nd^6]$ . The first term reflects a similar cost to that of standard LLE. The second term comes from a QR decomposition of the local hessian estimator.
3. **Partial Eigenvalue Decomposition.** Same as standard LLE

The overall complexity of standard HLLE is  $O[D \log(k)N \log(N)] + O[DNk^3] + O[Nd^6] + O[dN^2]$ .

- $N$  : number of training data points
- $D$  : input dimension
- $k$  : number of nearest neighbors
- $d$  : output dimension

## Spectral Embedding

Spectral Embedding is an approach to calculating a non-linear embedding. Scikit-learn implements Laplacian Eigenmaps, which finds a low dimensional representation of the data using a spectral decomposition of the graph Laplacian. The graph generated can be considered as a discrete approximation of the low dimensional manifold in the high dimensional space. Minimization of a cost function based on the graph ensures that points close to each other on the manifold are mapped close to each other in the low dimensional space, preserving local distances. Spectral embedding can be performed with the function `spectral_embedding` or its object-oriented counterpart `SpectralEmbedding`.

### Complexity

The Spectral Embedding (Laplacian Eigenmaps) algorithm comprises three stages:

1. **Weighted Graph Construction.** Transform the raw input data into graph representation using affinity (adjacency) matrix representation.
2. **Graph Laplacian Construction.** unnormalized Graph Laplacian is constructed as  $L = D - A$  for and normalized one as  $L = D^{-\frac{1}{2}}(D - A)D^{-\frac{1}{2}}$ .
3. **Partial Eigenvalue Decomposition.** Eigenvalue decomposition is done on graph Laplacian

The overall complexity of spectral embedding is  $O[D \log(k)N \log(N)] + O[DNk^3] + O[dN^2]$ .

- $N$  : number of training data points
- $D$  : input dimension
- $k$  : number of nearest neighbors
- $d$  : output dimension

## Local Tangent Space Alignment

Though not technically a variant of LLE, Local tangent space alignment (LTSA) is algorithmically similar enough to LLE that it can be put in this category. Rather than focusing on preserving neighborhood distances as in LLE, LTSA seeks to characterize the local geometry at each neighborhood via its tangent space, and performs a global optimization to align these local tangent spaces to learn the embedding. LTSA can be performed with function `locally_linear_embedding` or its object-oriented counterpart `LocallyLinearEmbedding`, with the keyword `method = 'ltsa'`.

### Complexity

The LTSA algorithm comprises three stages:

1. **Nearest Neighbors Search.** Same as standard LLE
2. **Weight Matrix Construction.** Approximately  $O[DNk^3] + O[k^2d]$ . The first term reflects a similar cost to that of standard LLE.
3. **Partial Eigenvalue Decomposition.** Same as standard LLE

The overall complexity of standard LTSA is  $O[D \log(k)N \log(N)] + O[DNk^3] + O[k^2d] + O[dN^2]$ .

- $N$  : number of training data points
- $D$  : input dimension
- $k$  : number of nearest neighbors
- $d$  : output dimension

## Multi-dimensional Scaling (MDS)

Multidimensional scaling ([MDS](#)) seeks a low-dimensional representation of the data in which the distances respect well the distances in the original high-dimensional space.

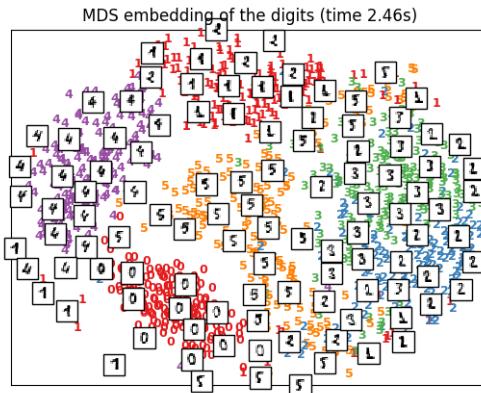

In general, is a technique used for analyzing similarity or dissimilarity data. [MDS](#) attempts to model similarity or dissimilarity data as distances in a geometric spaces. The data can be ratings of similarity between objects, interaction frequencies of molecules, or trade indices between countries.

There exists two types of MDS algorithm: metric and non metric. In the scikit-learn, the class [MDS](#) implements both. In Metric MDS, the input similarity matrix arises from a metric (and thus respects the triangular inequality), the distances between output two points are then set to be as close as possible to the similarity or dissimilarity data. In the non-metric version, the algorithms will try to preserve the order of the distances, and hence seek for a monotonic relationship between the distances in the embedded space and the similarities/dissimilarities.

Let  $S$  be the similarity matrix, and  $X$  the coordinates of the  $n$  input points. Disparities  $\hat{d}_{ij}$  are transformation of the similarities chosen in some optimal ways. The objective, called the stress, is then defined by  $\sum_{i < j} d_{ij}(X) - \hat{d}_{ij}(X)$

### Metric MDS

The simplest metric [MDS](#) model, called *absolute MDS*, disparities are defined by  $\hat{d}_{ij} = S_{ij}$ . With absolute MDS, the value  $S_{ij}$  should then correspond exactly to the distance between point  $i$  and  $j$  in the embedding point.

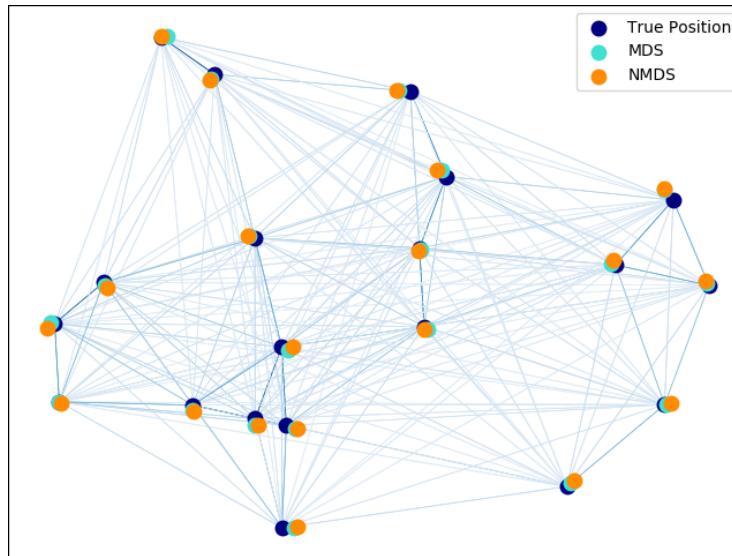

Most commonly, disparities are set to  $\hat{d}_{ij} = bS_{ij}$ .

## Nonmetric MDS

Non metric MDS focuses on the ordination of the data. If  $S_{ij} < S_{kl}$ , then the embedding should enforce  $d_{ij} < d_{jk}$ . A simple algorithm to enforce that is to use a monotonic regression of  $d_{ij}$  on  $S_{ij}$ , yielding disparities  $\hat{d}_{ij}$  in the same order as  $S_{ij}$ .

A trivial solution to this problem is to set all the points on the origin. In order to avoid that, the disparities  $\hat{d}_{ij}$  are normalized.

## t-distributed Stochastic Neighbor Embedding (t-SNE)

t-SNE ([TSNE](#)) converts affinities of data points to probabilities. The affinities in the original space are represented by Gaussian joint probabilities and the affinities in the embedded space are represented by Student's t-distributions. This allows t-SNE to be particularly sensitive to local structure and has a few other advantages over existing techniques:

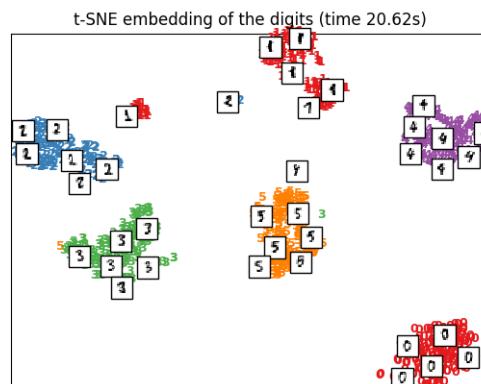

- Revealing the structure at many scales on a single map
- Revealing data that lie in multiple, different, manifolds or clusters
- Reducing the tendency to crowd points together at the center

While Isomap, LLE and variants are best suited to unfold a single continuous low dimensional manifold, t-SNE will focus on the local structure of the data and will tend to extract clustered local groups of samples as highlighted on the S-curve example. This ability to group samples based on the local structure might be beneficial to visually disentangle a dataset that comprises several manifolds at once as is the case in the digits dataset.

The Kullback-Leibler (KL) divergence of the joint probabilities in the original space and the embedded space will be minimized by gradient descent. Note that the KL divergence is not convex, i.e. multiple restarts with different initializations will end up in local minima of the KL divergence. Hence, it is sometimes useful to try different seeds and select the embedding with the lowest KL divergence.

The disadvantages to using t-SNE are roughly:

- t-SNE is computationally expensive, and can take several hours on million-sample datasets where PCA will finish in seconds or minutes
- The Barnes-Hut t-SNE method is limited to two or three dimensional embeddings.
- The algorithm is stochastic and multiple restarts with different seeds can yield different embeddings. However, it is perfectly legitimate to pick the embedding with the least error.
- Global structure is not explicitly preserved. This problem is mitigated by initializing points with PCA (using `init='pca'`).

## Optimizing t-SNE

The main purpose of t-SNE is visualization of high-dimensional data. Hence, it works best when the data will be embedded on two or three dimensions.

Optimizing the KL divergence can be a little bit tricky sometimes. There are five parameters that control the optimization of t-SNE and therefore possibly the quality of the resulting embedding:

- perplexity
- early exaggeration factor
- learning rate
- maximum number of iterations
- angle (not used in the exact method)

The perplexity is defined as  $k = 2^S$  where  $S$  is the Shannon entropy of the conditional probability distribution. The perplexity of a  $k$ -sided die is  $k$ , so that  $k$  is effectively the number of nearest neighbors t-SNE considers when generating the conditional probabilities. Larger perplexities lead to more nearest neighbors and less sensitive to small structure. Conversely a lower perplexity considers a smaller number of neighbors, and thus ignores more global information in favour of the local neighborhood. As dataset sizes get larger more points will be required to get a reasonable sample of the local neighborhood, and hence larger perplexities may be required. Similarly noisier datasets will require larger perplexity values to encompass enough local neighbors to see beyond the background noise.

The maximum number of iterations is usually high enough and does not need any tuning. The optimization consists of two phases: the early exaggeration phase and the final optimization. During early exaggeration the joint probabilities in the original space will be artificially increased by multiplication with a given factor. Larger factors result in larger gaps between natural clusters in the data. If the factor is too high, the KL divergence could increase during this phase. Usually it does not have to be tuned. A critical parameter is the learning rate. If it is too low gradient descent will get stuck in a bad local minimum. If it is too high the KL divergence will increase during optimization. More tips can be found in Laurens van der Maaten's FAQ (see references). The last parameter, angle, is a tradeoff between performance and accuracy. Larger angles imply that we can approximate larger regions by a single point, leading to better speed but less accurate results.

"[How to Use t-SNE Effectively](#)" provides a good discussion of the effects of the various parameters, as well as interactive plots to explore the effects of different parameters.

## Barnes-Hut t-SNE

The Barnes-Hut t-SNE that has been implemented here is usually much slower than other manifold learning algorithms. The optimization is quite difficult and the computation of the gradient is  $O[dN\log(N)]$ , where  $d$  is the number of output dimensions and  $N$  is the number of samples. The Barnes-Hut method improves on the exact method where t-SNE complexity is  $O[dN^2]$ , but has several other notable differences:

- The Barnes-Hut implementation only works when the target dimensionality is 3 or less. The 2D case is typical when building visualizations.
- Barnes-Hut only works with dense input data. Sparse data matrices can only be embedded with the exact method or can be approximated by a dense low rank projection for instance using `sklearn.decomposition.TruncatedSVD`
- Barnes-Hut is an approximation of the exact method. The approximation is parameterized with the angle parameter, therefore the angle parameter is unused when method="exact"
- Barnes-Hut is significantly more scalable. Barnes-Hut can be used to embed hundred of thousands of data points while the exact method can handle thousands of samples before becoming computationally intractable

For visualization purpose (which is the main use case of t-SNE), using the Barnes-Hut method is strongly recommended. The exact t-SNE method is useful for checking the theoretically properties of the embedding possibly in higher dimensional space but limit to small datasets due to computational constraints.

Also note that the digits labels roughly match the natural grouping found by t-SNE while the linear 2D projection of the PCA model yields a representation where label regions largely overlap. This is a strong clue that this data can be well separated by non linear methods that focus on the local structure (e.g. an SVM with a Gaussian RBF kernel). However, failing to visualize well separated homogeneously labeled groups with t-SNE in 2D does not necessarily imply that the data cannot be correctly classified by a supervised model. It might be the case that 2 dimensions are not enough low to accurately represents the internal structure of the data.

## Tips on practical use

- Make sure the same scale is used over all features. Because manifold learning methods are based on a nearest-neighbor search, the algorithm may perform poorly otherwise. See [StandardScaler](#) for convenient ways of scaling heterogeneous data.
- The reconstruction error computed by each routine can be used to choose the optimal output dimension. For a  $d$ -dimensional manifold embedded in a  $D$ -dimensional parameter space, the reconstruction error will decrease as `n_components` is increased until `n_components == d`.
- Note that noisy data can “short-circuit” the manifold, in essence acting as a bridge between parts of the manifold that would otherwise be well-separated. Manifold learning on noisy and/or incomplete data is an active area of research.
- Certain input configurations can lead to singular weight matrices, for example when more than two points in the dataset are identical, or when the data is split into disjointed groups. In this case, `solver='arpack'` will fail to find the null space. The easiest way to address this is to use `solver='dense'` which will work on a singular matrix, though it may be very slow depending on the number of input points. Alternatively, one can attempt to understand the source of the singularity: if it is due to disjoint sets, increasing `n_neighbors` may help. If it is due to identical points in the dataset, removing these points may help.

### See also:

[Totally Random Trees Embedding](#) can also be useful to derive non-linear representations of feature space, also it does not perform dimensionality reduction.

## 3.2.3 Clustering

Clustering of unlabeled data can be performed with the module [`sklearn.cluster`](#).

Each clustering algorithm comes in two variants: a class, that implements the `fit` method to learn the clusters on train data, and a function, that, given train data, returns an array of integer labels corresponding to the different clusters. For the class, the labels over the training data can be found in the `labels_` attribute.

## Input data

One important thing to note is that the algorithms implemented in this module can take different kinds of matrix as input. All the methods accept standard data matrices of shape [n\_samples, n\_features]. These can be obtained from the classes in the `sklearn.feature_extraction` module. For `AffinityPropagation`, `SpectralClustering` and `DBSCAN` one can also input similarity matrices of shape [n\_samples, n\_samples]. These can be obtained from the functions in the `sklearn.metrics.pairwise` module.

## Overview of clustering methods

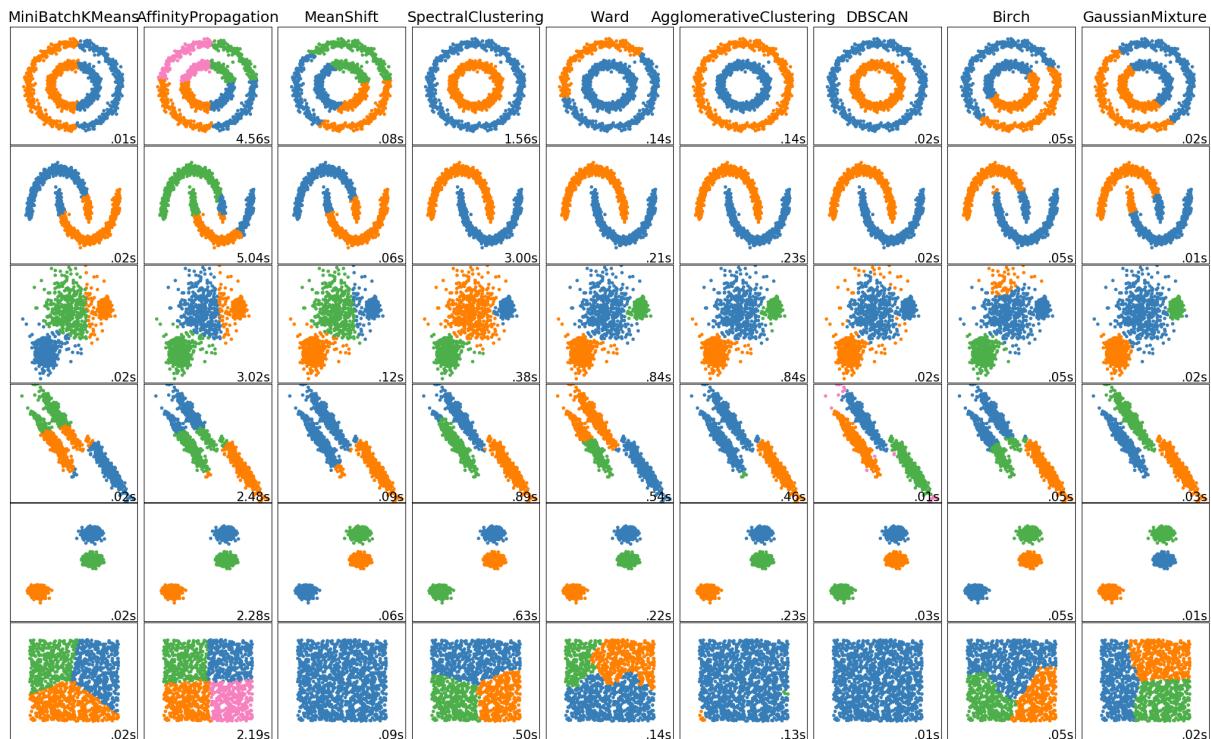

Fig. 3.4: A comparison of the clustering algorithms in scikit-learn

Method name	Parameters	Scalability	Usecase	Geometry (metric used)
<i>K-Means</i>	number of clusters	Very large n_samples, medium n_clusters with <i>MiniBatch code</i>	General-purpose, even cluster size, flat geometry, not too many clusters	Distances between points
<i>Affinity propagation</i>	damping, sample preference	Not scalable with n_samples	Many clusters, uneven cluster size, non-flat geometry	Graph distance (e.g. nearest-neighbor graph)
<i>Mean-shift</i>	bandwidth	Not scalable with n_samples	Many clusters, uneven cluster size, non-flat geometry	Distances between points
<i>Spectral clustering</i>	number of clusters	Medium n_samples, small n_clusters	Few clusters, even cluster size, non-flat geometry	Graph distance (e.g. nearest-neighbor graph)
<i>Ward hierarchical clustering</i>	number of clusters	Large n_samples and n_clusters	Many clusters, possibly connectivity constraints	Distances between points
<i>Agglomerative clustering</i>	number of clusters, linkage type, distance	Large n_samples and n_clusters	Many clusters, possibly connectivity constraints, non Euclidean distances	Any pairwise distance
<i>DBSCAN</i>	neighborhood size	Very large n_samples, medium n_clusters	Non-flat geometry, uneven cluster sizes	Distances between nearest points
<i>Gaussian mixtures</i>	many	Not scalable	Flat geometry, good for density estimation	Mahalanobis distances to centers
<i>Birch</i>	branching factor, threshold, optional global clusterer.	Large n_clusters and n_samples	Large dataset, outlier removal, data reduction.	Euclidean distance between points

Non-flat geometry clustering is useful when the clusters have a specific shape, i.e. a non-flat manifold, and the standard euclidean distance is not the right metric. This case arises in the two top rows of the figure above.

Gaussian mixture models, useful for clustering, are described in [another chapter of the documentation](#) dedicated to mixture models. KMeans can be seen as a special case of Gaussian mixture model with equal covariance per component.

## K-means

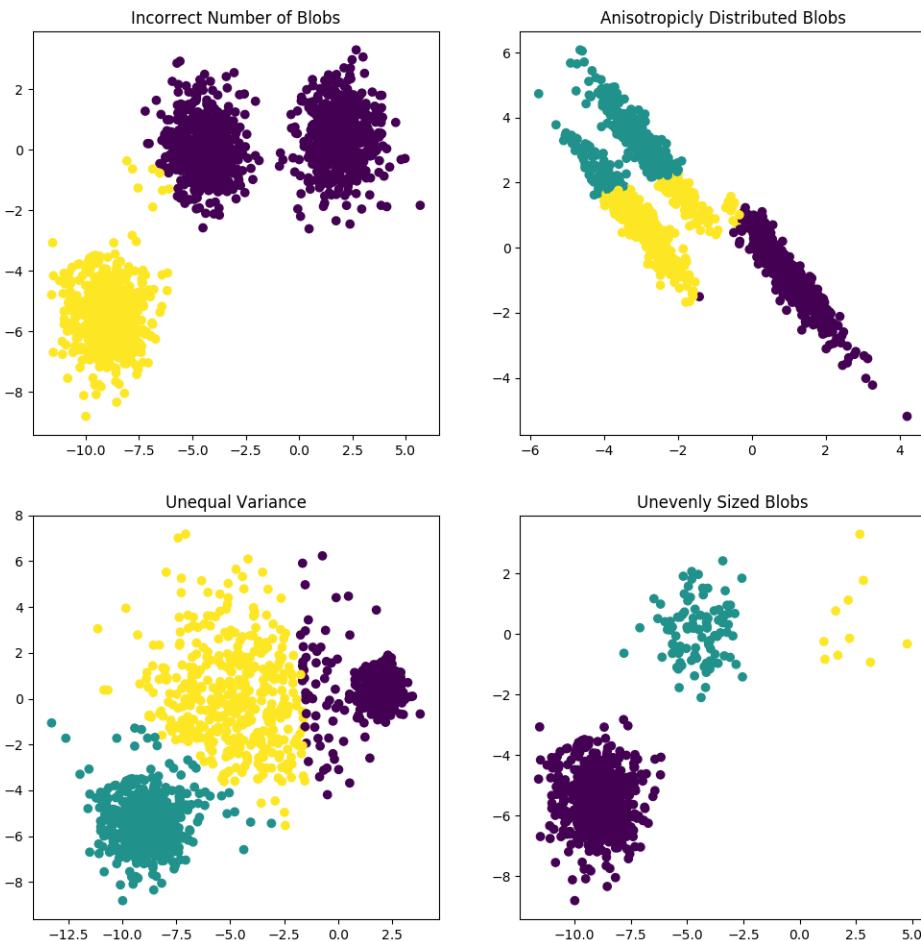

The *KMeans* algorithm clusters data by trying to separate samples in n groups of equal variance, minimizing a criterion known as the *inertia* or within-cluster sum-of-squares. This algorithm requires the number of clusters to be specified. It scales well to large number of samples and has been used across a large range of application areas in many different fields.

The k-means algorithm divides a set of  $N$  samples  $X$  into  $K$  disjoint clusters  $C$ , each described by the mean  $\mu_j$  of the samples in the cluster. The means are commonly called the cluster “centroids”; note that they are not, in general, points from  $X$ , although they live in the same space. The K-means algorithm aims to choose centroids that minimise the *inertia*, or within-cluster sum of squared criterion:

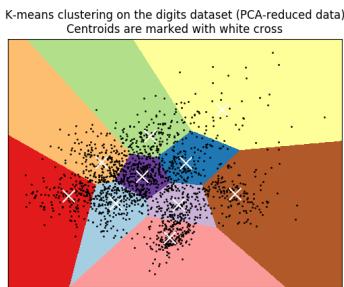

$$\sum_{i=0}^n \min_{\mu_j \in C} (\|x_j - \mu_i\|^2)$$

Inertia, or the within-cluster sum of squares criterion, can be recognized as a measure of how internally coherent clusters are. It suffers from various drawbacks:

- Inertia makes the assumption that clusters are convex and isotropic, which is not always the case. It responds poorly to elongated clusters, or manifolds with irregular shapes.
- Inertia is not a normalized metric: we just know that lower values are better and zero is optimal. But in very high-dimensional spaces, Euclidean distances tend to become inflated (this is an instance of the so-called “curse of dimensionality”). Running a dimensionality reduction algorithm such as [PCA](#) prior to k-means clustering can alleviate this problem and speed up the computations.

K-means is often referred to as Lloyd's algorithm. In basic terms, the algorithm has three steps. The first step chooses the initial centroids, with the most basic method being to choose  $k$  samples from the dataset  $X$ . After initialization, K-means consists of looping between the two other steps. The first step assigns each sample to its nearest centroid. The second step creates new centroids by taking the mean value of all of the samples assigned to each previous centroid. The difference between the old and the new centroids are computed and the algorithm repeats these last two steps until this value is less than a threshold. In other words, it repeats until the centroids do not move significantly.

K-means is equivalent to the expectation-maximization algorithm with a small, all-equal, diagonal covariance matrix.

The algorithm can also be understood through the concept of [Voronoi diagrams](#). First the Voronoi diagram of the points is calculated using the current centroids. Each segment in the Voronoi diagram becomes a separate cluster. Secondly, the centroids are updated to the mean of each segment. The algorithm then repeats this until a stopping criterion is fulfilled. Usually, the algorithm stops when the relative decrease in the objective function between iterations is less than the given tolerance value. This is not the case in this implementation: iteration stops when centroids move less than the tolerance.

Given enough time, K-means will always converge, however this may be to a local minimum. This is highly dependent on the initialization of the centroids. As a result, the computation is often done several times, with different initializations of the centroids. One method to help address this issue is the k-means++ initialization scheme, which has been implemented in scikit-learn (use the `init='kmeans++'` parameter). This initializes the centroids to be (generally) distant from each other, leading to provably better results than random initialization, as shown in the reference.

A parameter can be given to allow K-means to be run in parallel, called `n_jobs`. Giving this parameter a positive value uses that many processors (default: 1). A value of -1 uses all available processors, with -2 using one less, and so on. Parallelization generally speeds up computation at the cost of memory (in this case, multiple copies of centroids need to be stored, one for each job).

**Warning:** The parallel version of K-Means is broken on OS X when `numpy` uses the *Accelerate* Framework. This is expected behavior: *Accelerate* can be called after a fork but you need to execv the subprocess with the Python binary (which multiprocessing does not do under posix).

K-means can be used for vector quantization. This is achieved using the `transform` method of a trained model of `KMeans`.

## Mini Batch K-Means

The `MiniBatchKMeans` is a variant of the `KMeans` algorithm which uses mini-batches to reduce the computation time, while still attempting to optimise the same objective function. Mini-batches are subsets of the input data, randomly sampled in each training iteration. These mini-batches drastically reduce the amount of computation required to converge to a local solution. In contrast to other algorithms that reduce the convergence time of k-means, mini-batch k-means produces results that are generally only slightly worse than the standard algorithm.

The algorithm iterates between two major steps, similar to vanilla k-means. In the first step,  $b$  samples are drawn randomly from the dataset, to form a mini-batch. These are then assigned to the nearest centroid. In the second step, the centroids are updated. In contrast to k-means, this is done on a per-sample basis. For each sample in the mini-batch, the assigned centroid is updated by taking the streaming average of the sample and all previous samples assigned to that centroid. This has the effect of decreasing the rate of change for a centroid over time. These steps are performed until convergence or a predetermined number of iterations is reached.

`MiniBatchKMeans` converges faster than `KMeans`, but the quality of the results is reduced. In practice this difference in quality can be quite small, as shown in the example and cited reference.

## Affinity Propagation

`AffinityPropagation` creates clusters by sending messages between pairs of samples until convergence. A dataset is then described using a small number of exemplars, which are identified as those most representative of other

samples. The messages sent between pairs represent the suitability for one sample to be the exemplar of the other, which is updated in response to the values from other pairs. This updating happens iteratively until convergence, at which point the final exemplars are chosen, and hence the final clustering is given.

Affinity Propagation can be interesting as it chooses the number of clusters based on the data provided. For this purpose, the two important parameters are the *preference*, which controls how many exemplars are used, and the *damping factor*.

The main drawback of Affinity Propagation is its complexity. The algorithm has a time complexity of the order  $O(N^2T)$ , where  $N$  is the number of samples and  $T$  is the number of iterations until convergence. Further, the memory complexity is of the order  $O(N^2)$  if a dense similarity matrix is used, but reducible if a sparse similarity matrix is used. This makes Affinity Propagation most appropriate for small to medium sized datasets.

#### Examples:

- [Demo of affinity propagation clustering algorithm](#): Affinity Propagation on a synthetic 2D datasets with 3 classes.
- [Visualizing the stock market structure](#) Affinity Propagation on Financial time series to find groups of companies

**Algorithm description:** The messages sent between points belong to one of two categories. The first is the responsibility  $r(i, k)$ , which is the accumulated evidence that sample  $k$  should be the exemplar for sample  $i$ . The second is the availability  $a(i, k)$  which is the accumulated evidence that sample  $i$  should choose sample  $k$  to be its exemplar, and considers the values for all other samples that  $k$  should be an exemplar. In this way, exemplars are chosen by samples if they are (1) similar enough to many samples and (2) chosen by many samples to be representative of themselves.

More formally, the responsibility of a sample  $k$  to be the exemplar of sample  $i$  is given by:

$$r(i, k) \leftarrow s(i, k) - \max[a(i, \hat{k}) + s(i, \hat{k}) \forall \hat{k} \neq k]$$

Where  $s(i, k)$  is the similarity between samples  $i$  and  $k$ . The availability of sample  $k$  to be the exemplar of sample  $i$  is given by:

$$a(i, k) \leftarrow \min[0, r(k, k) + \sum_{\substack{i \text{ s.t. } i \notin \{i, k\}}} r(i, k)]$$

To begin with, all values for  $r$  and  $a$  are set to zero, and the calculation of each iterates until convergence.

## Mean Shift

*MeanShift* clustering aims to discover *blobs* in a smooth density of samples. It is a centroid based algorithm, which works by updating candidates for centroids to be the mean of the points within a given region. These candidates are then filtered in a post-processing stage to eliminate near-duplicates to form the final set of centroids.

Given a candidate centroid  $x_i$  for iteration  $t$ , the candidate is updated according to the following equation:

$$x_i^{t+1} = x_i^t + m(x_i^t)$$

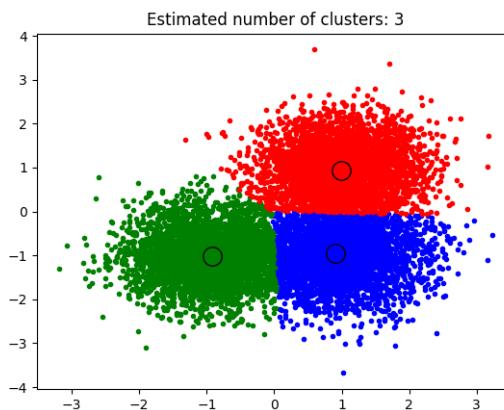

Where  $N(x_i)$  is the neighborhood of samples within a given distance around  $x_i$  and  $m$  is the *mean shift* vector that is computed for each centroid that points towards a region of the maximum increase in the density of points. This is computed using the following equation, effectively updating a centroid to be the mean of the samples within its neighborhood:

$$m(x_i) = \frac{\sum_{x_j \in N(x_i)} K(x_j - x_i)x_j}{\sum_{x_j \in N(x_i)} K(x_j - x_i)}$$

The algorithm automatically sets the number of clusters, instead of relying on a parameter `bandwidth`, which dictates the size of the region to search through. This parameter can be set manually, but can be estimated using the provided `estimate_bandwidth` function, which is called if the bandwidth is not set.

The algorithm is not highly scalable, as it requires multiple nearest neighbor searches during the execution of the algorithm. The algorithm is guaranteed to converge, however the algorithm will stop iterating when the change in centroids is small.

Labelling a new sample is performed by finding the nearest centroid for a given sample.

## Spectral clustering

`SpectralClustering` does a low-dimension embedding of the affinity matrix between samples, followed by a KMeans in the low dimensional space. It is especially efficient if the affinity matrix is sparse and the `pyamg` module is installed. SpectralClustering requires the number of clusters to be specified. It works well for a small number of clusters but is not advised when using many clusters.

For two clusters, it solves a convex relaxation of the `normalised cuts` problem on the similarity graph: cutting the graph in two so that the weight of the edges cut is small compared to the weights of the edges inside each cluster. This criteria is especially interesting when working on images: graph vertices are pixels, and edges of the similarity graph are a function of the gradient of the image.

### Warning: Transforming distance to well-behaved similarities

Note that if the values of your similarity matrix are not well distributed, e.g. with negative values or with a distance matrix rather than a similarity, the spectral problem will be singular and the problem not solvable. In which case it is advised to apply a transformation to the entries of the matrix. For instance, in the case of a signed distance matrix, is common to apply a heat kernel:

```
similarity = np.exp(-beta * distance / distance.std())
```

See the examples for such an application.

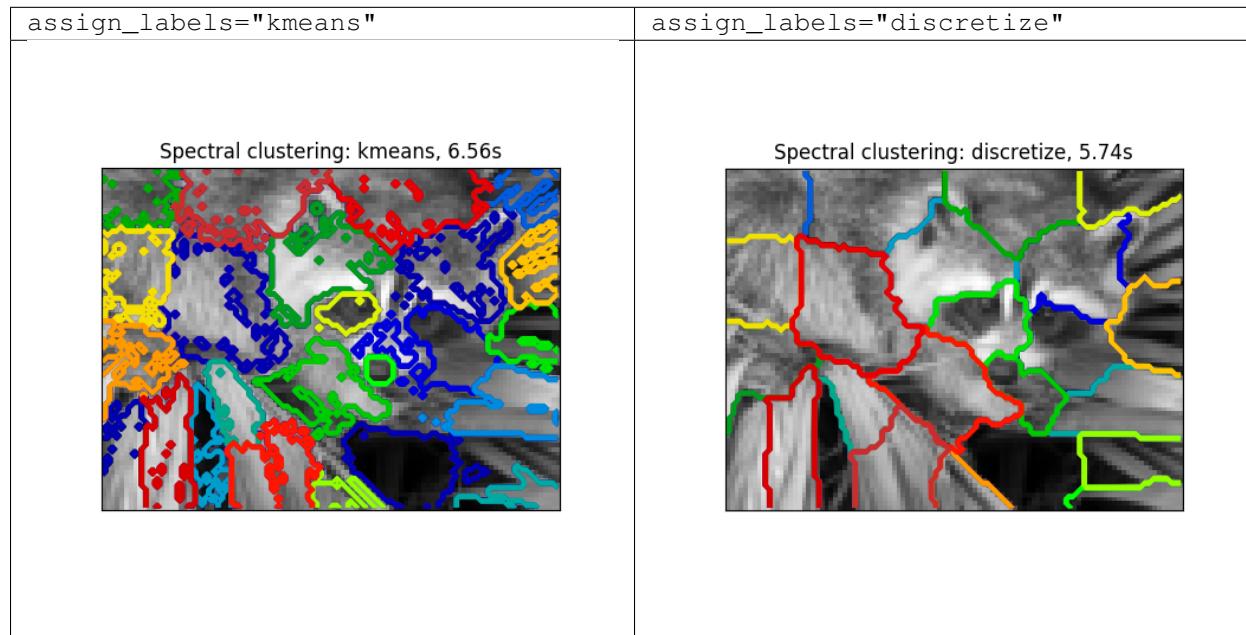

### Examples:

- *Spectral clustering for image segmentation*: Segmenting objects from a noisy background using spectral clustering.
- *Segmenting the picture of a raccoon face in regions*: Spectral clustering to split the image of the raccoon face in regions.

## Different label assignment strategies

Different label assignment strategies can be used, corresponding to the `assign_labels` parameter of `SpectralClustering`. The "kmeans" strategy can match finer details of the data, but it can be more unstable. In particular, unless you control the `random_state`, it may not be reproducible from run-to-run, as it depends

on a random initialization. On the other hand, the "discretize" strategy is 100% reproducible, but it tends to create parcels of fairly even and geometrical shape.

## Hierarchical clustering

Hierarchical clustering is a general family of clustering algorithms that build nested clusters by merging or splitting them successively. This hierarchy of clusters is represented as a tree (or dendrogram). The root of the tree is the unique cluster that gathers all the samples, the leaves being the clusters with only one sample. See the [Wikipedia page](#) for more details.

The `AgglomerativeClustering` object performs a hierarchical clustering using a bottom up approach: each observation starts in its own cluster, and clusters are successively merged together. The linkage criteria determines the metric used for the merge strategy:

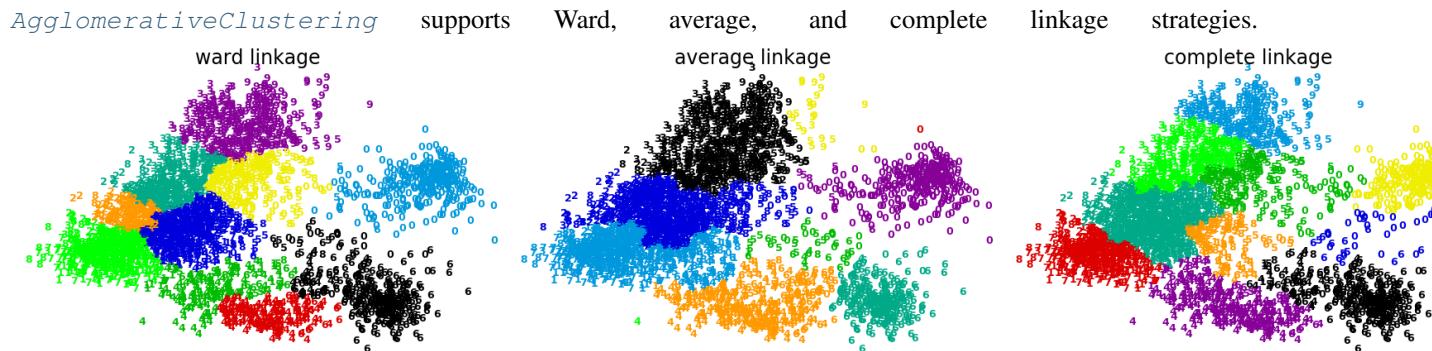

- **Ward** minimizes the sum of squared differences within all clusters. It is a variance-minimizing approach and in this sense is similar to the k-means objective function but tackled with an agglomerative hierarchical approach.
- **Maximum or complete linkage** minimizes the maximum distance between observations of pairs of clusters.
- **Average linkage** minimizes the average of the distances between all observations of pairs of clusters.

`AgglomerativeClustering` can also scale to large number of samples when it is used jointly with a connectivity matrix, but is computationally expensive when no connectivity constraints are added between samples: it considers at each step all the possible merges.

### FeatureAgglomeration

The `FeatureAgglomeration` uses agglomerative clustering to group together features that look very similar, thus decreasing the number of features. It is a dimensionality reduction tool, see [Unsupervised dimensionality reduction](#).

### Different linkage type: Ward, complete and average linkage

Agglomerative cluster has a “rich get richer” behavior that leads to uneven cluster sizes. In this regard, complete linkage is the worst strategy, and Ward gives the most regular sizes. However, the affinity (or distance used in clustering) cannot be varied with Ward, thus for non Euclidean metrics, average linkage is a good alternative.

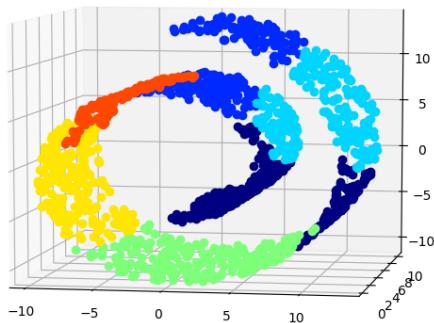

### Examples:

- [Various Agglomerative Clustering on a 2D embedding of digits](#): exploration of the different linkage strategies in a real dataset.

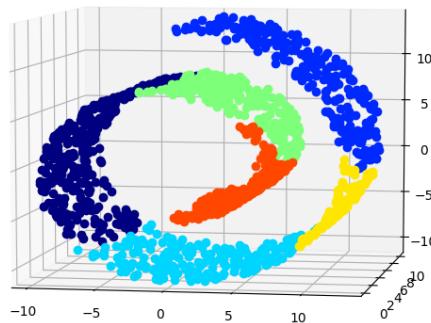

### Adding connectivity constraints

An interesting aspect of `AgglomerativeClustering` is that connectivity constraints can be added to this algorithm (only adjacent clusters can be merged together), through a connectivity matrix that defines for each sample the neighboring samples following a given structure of the data. For instance, in the swiss-roll example below, the connectivity constraints forbid the merging of points that are not adjacent on the swiss roll, and thus avoid forming clusters that extend across overlapping folds of the roll.

Without connectivity constraints (time 0.06s)

With connectivity constraints (time 0.14s)

These constraint are useful to impose a certain local structure, but they also make the algorithm faster, especially when the number of the samples is high.

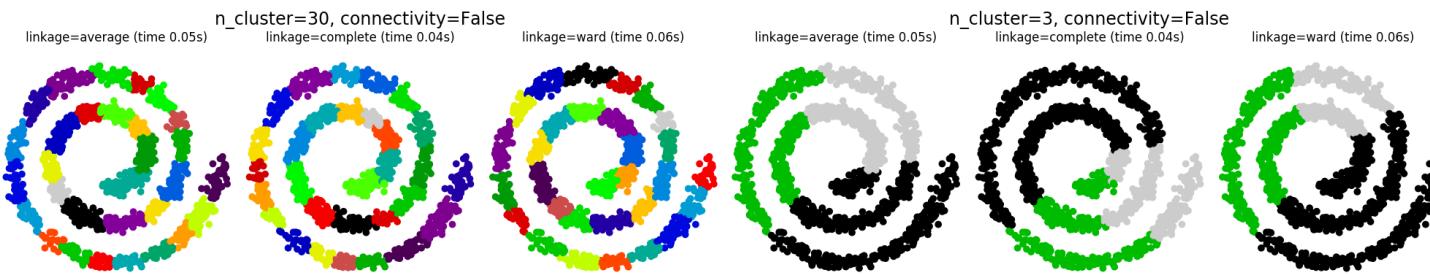

The connectivity constraints are imposed via an connectivity matrix: a scipy sparse matrix that has elements only at the intersection of a row and a column with indices of the dataset that should be connected. This matrix can be constructed from a-priori information: for instance, you may wish to cluster web pages by only merging pages with a link pointing from one to another. It can also be learned from the data, for instance using `sklearn.neighbors.kneighbors_graph` to restrict merging to nearest neighbors as in [this example](#), or using `sklearn.feature_extraction.image.grid_to_graph` to enable only merging of neighboring pixels on an image, as in the [raccoon face](#) example.

#### Examples:

- [A demo of structured Ward hierarchical clustering on a raccoon face image](#): Ward clustering to split the image of a raccoon face in regions.
- [Hierarchical clustering: structured vs unstructured ward](#): Example of Ward algorithm on a swiss-roll, comparison of structured approaches versus unstructured approaches.
- [Feature agglomeration vs. univariate selection](#): Example of dimensionality reduction with feature agglomeration based on Ward hierarchical clustering.
- [Agglomerative clustering with and without structure](#)

#### Warning: Connectivity constraints with average and complete linkage

Connectivity constraints and complete or average linkage can enhance the ‘rich getting richer’ aspect of agglomerative clustering, particularly so if they are built with `sklearn.neighbors.kneighbors_graph`. In the limit of a small number of clusters, they tend to give a few macroscopically occupied clusters and almost empty ones. (see the discussion in [Agglomerative clustering with and without structure](#)).

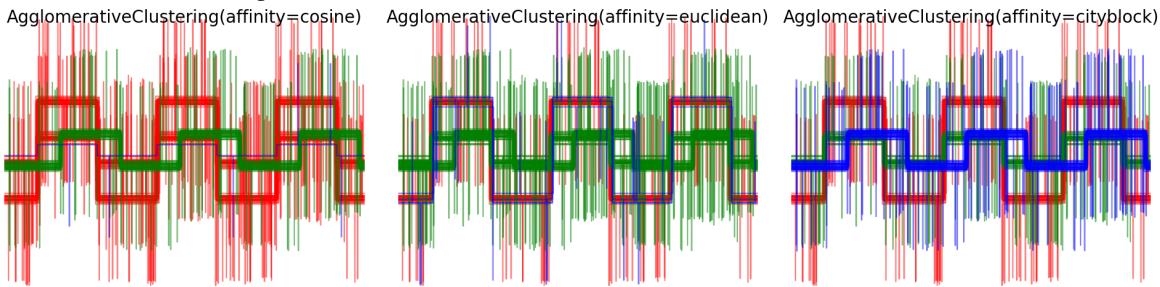

### Varying the metric

Average and complete linkage can be used with a variety of distances (or affinities), in particular Euclidean distance ( $l2$ ), Manhattan distance (or Cityblock, or  $l1$ ), cosine distance, or any precomputed affinity matrix.

- $l1$  distance is often good for sparse features, or sparse noise: ie many of the features are zero, as in text mining using occurrences of rare words.
- *cosine* distance is interesting because it is invariant to global scalings of the signal.

The guidelines for choosing a metric is to use one that maximizes the distance between samples in different classes, and minimizes that within each class.

### Examples:

- *Agglomerative clustering with different metrics*

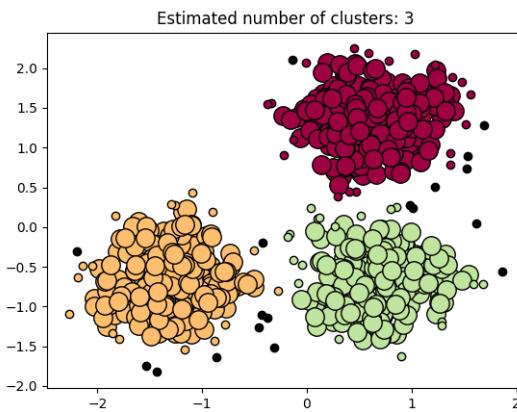

## DBSCAN

The [DBSCAN](#) algorithm views clusters as areas of high density separated by areas of low density. Due to this rather generic view, clusters found by DBSCAN can be any shape, as opposed to k-means which assumes that clusters are convex shaped. The central component to the DBSCAN is the concept of *core samples*, which are samples that are in areas of high density. A cluster is therefore a set of core samples, each close to each other (measured by some distance measure) and a set of non-core samples that are close to a core sample (but are not themselves core samples). There are two parameters to the algorithm, `min_samples` and `eps`, which define formally what we mean when we say *dense*. Higher `min_samples` or lower `eps` indicate higher density necessary to form a cluster.

More formally, we define a core sample as being a sample in the dataset such that there exist `min_samples` other samples within a distance of `eps`, which are defined as *neighbors* of the core sample. This tells us that the core sample is in a dense area of the vector space. A cluster is a set of core samples that can be built by recursively taking a core sample, finding all of its neighbors that are core samples, finding all of *their* neighbors that are core samples, and so on. A cluster also has a set of non-core samples, which are samples that are neighbors of a core sample in the cluster but are not themselves core samples. Intuitively, these samples are on the fringes of a cluster.

Any core sample is part of a cluster, by definition. Any sample that is not a core sample, and is at least  $\text{eps}$  in distance from any core sample, is considered an outlier by the algorithm.

In the figure below, the color indicates cluster membership, with large circles indicating core samples found by the algorithm. Smaller circles are non-core samples that are still part of a cluster. Moreover, the outliers are indicated by black points below.

### Examples:

- [Demo of DBSCAN clustering algorithm](#)

### Implementation

The DBSCAN algorithm is deterministic, always generating the same clusters when given the same data in the same order. However, the results can differ when data is provided in a different order. First, even though the core samples will always be assigned to the same clusters, the labels of those clusters will depend on the order in which those samples are encountered in the data. Second and more importantly, the clusters to which non-core samples are assigned can differ depending on the data order. This would happen when a non-core sample has a distance lower than  $\text{eps}$  to two core samples in different clusters. By the triangular inequality, those two core samples must be more distant than  $\text{eps}$  from each other, or they would be in the same cluster. The non-core sample is assigned to whichever cluster is generated first in a pass through the data, and so the results will depend on the data ordering.

The current implementation uses ball trees and kd-trees to determine the neighborhood of points, which avoids calculating the full distance matrix (as was done in scikit-learn versions before 0.14). The possibility to use custom metrics is retained; for details, see `NearestNeighbors`.

### Memory consumption for large sample sizes

This implementation is by default not memory efficient because it constructs a full pairwise similarity matrix in the case where kd-trees or ball-trees cannot be used (e.g. with sparse matrices). This matrix will consume  $n^2$  floats. A couple of mechanisms for getting around this are:

- A sparse radius neighborhood graph (where missing entries are presumed to be out of  $\text{eps}$ ) can be precomputed in a memory-efficient way and `dbscan` can be run over this with `metric='precomputed'`.
- The dataset can be compressed, either by removing exact duplicates if these occur in your data, or by using BIRCH. Then you only have a relatively small number of representatives for a large number of points. You

can then provide a `sample_weight` when fitting DBSCAN.

## Birch

The `Birch` builds a tree called the Characteristic Feature Tree (CFT) for the given data. The data is essentially lossy compressed to a set of Characteristic Feature nodes (CF Nodes). The CF Nodes have a number of subclusters called Characteristic Feature subclusters (CF Subclusters) and these CF Subclusters located in the non-terminal CF Nodes can have CF Nodes as children.

The CF Subclusters hold the necessary information for clustering which prevents the need to hold the entire input data in memory. This information includes:

- Number of samples in a subcluster.
- Linear Sum - A n-dimensional vector holding the sum of all samples
- Squared Sum - Sum of the squared L2 norm of all samples.
- Centroids - To avoid recalculation linear sum / `n_samples`.
- Squared norm of the centroids.

The Birch algorithm has two parameters, the threshold and the branching factor. The branching factor limits the number of subclusters in a node and the threshold limits the distance between the entering sample and the existing subclusters.

This algorithm can be viewed as an instance or data reduction method, since it reduces the input data to a set of subclusters which are obtained directly from the leaves of the CFT. This reduced data can be further processed by feeding it into a global clusterer. This global clusterer can be set by `n_clusters`. If `n_clusters` is set to None, the subclusters from the leaves are directly read off, otherwise a global clustering step labels these subclusters into global clusters (labels) and the samples are mapped to the global label of the nearest subcluster.

### Algorithm description:

- A new sample is inserted into the root of the CF Tree which is a CF Node. It is then merged with the subcluster of the root, that has the smallest radius after merging, constrained by the threshold and branching factor conditions. If the subcluster has any child node, then this is done repeatedly till it reaches a leaf. After finding the nearest subcluster in the leaf, the properties of this subcluster and the parent subclusters are recursively updated.
- If the radius of the subcluster obtained by merging the new sample and the nearest subcluster is greater than the square of the threshold and if the number of subclusters is greater than the branching factor, then a space is temporarily allocated to this new sample. The two farthest subclusters are taken and the subclusters are divided into two groups on the basis of the distance between these subclusters.
- If this split node has a parent subcluster and there is room for a new subcluster, then the parent is split into two. If there is no room, then this node is again split into two and the process is continued recursively, till it reaches the root.

### Birch or MiniBatchKMeans?

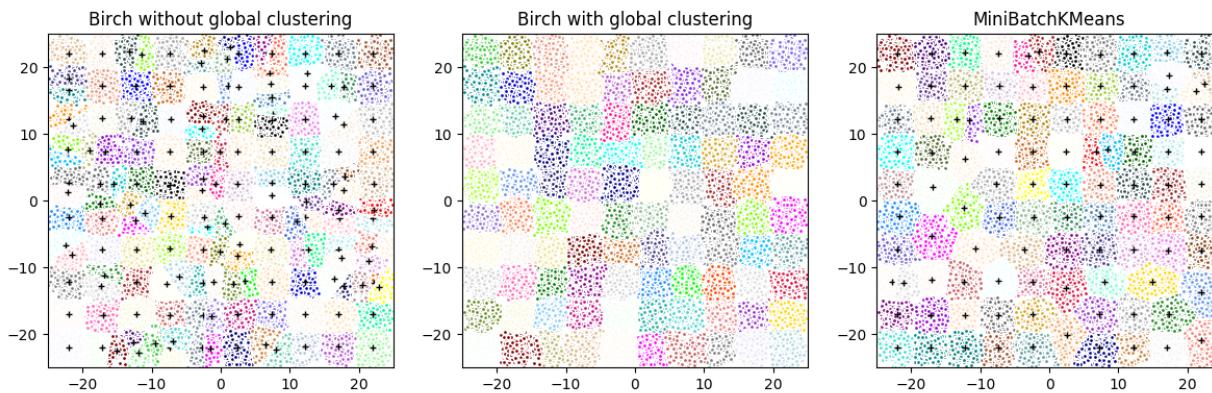

- Birch does not scale very well to high dimensional data. As a rule of thumb if `n_features` is greater than twenty, it is generally better to use MiniBatchKMeans.

- If the number of instances of data needs to be reduced, or if one wants a large number of subclusters either as a preprocessing step or otherwise, Birch is more useful than MiniBatchKMeans.

### How to use partial\_fit?

To avoid the computation of global clustering, for every call of `partial_fit` the user is advised

1. To set `n_clusters=None` initially
2. Train all data by multiple calls to `partial_fit`.
3. Set `n_clusters` to a required value using `brc.set_params(n_clusters=n_clusters)`.
4. Call `partial_fit` finally with no arguments, i.e `brc.partial_fit()` which performs the global clustering.

## Clustering performance evaluation

Evaluating the performance of a clustering algorithm is not as trivial as counting the number of errors or the precision and recall of a supervised classification algorithm. In particular any evaluation metric should not take the absolute values of the cluster labels into account but rather if this clustering define separations of the data similar to some ground truth set of classes or satisfying some assumption such that members belong to the same class are more similar than members of different classes according to some similarity metric.

### Adjusted Rand index

Given the knowledge of the ground truth class assignments `labels_true` and our clustering algorithm assignments of the same samples `labels_pred`, the **adjusted Rand index** is a function that measures the **similarity** of the two assignments, ignoring permutations and **with chance normalization**:

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]
```

```
>>> metrics.adjusted_rand_score(labels_true, labels_pred)
0.24...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3, and get the same score:

```
>>> labels_pred = [1, 1, 0, 0, 3, 3]
>>> metrics.adjusted_rand_score(labels_true, labels_pred)
0.24...
```

Furthermore, `adjusted_rand_score` is **symmetric**: swapping the argument does not change the score. It can thus be used as a **consensus measure**:

```
>>> metrics.adjusted_rand_score(labels_pred, labels_true)
0.24...
```

Perfect labeling is scored 1.0:

```
>>> labels_pred = labels_true[:]
>>> metrics.adjusted_rand_score(labels_true, labels_pred)
1.0
```

Bad (e.g. independent labelings) have negative or close to 0.0 scores:

```
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]
>>> metrics.adjusted_rand_score(labels_true, labels_pred)
-0.12...
```

## Advantages

- **Random (uniform) label assignments have a ARI score close to 0.0** for any value of `n_clusters` and `n_samples` (which is not the case for raw Rand index or the V-measure for instance).
- **Bounded range [-1, 1]**: negative values are bad (independent labelings), similar clusterings have a positive ARI, 1.0 is the perfect match score.
- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes.

## Drawbacks

- Contrary to inertia, **ARI requires knowledge of the ground truth classes** while is almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

However ARI can also be useful in a purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection (TODO).

### Examples:

- *Adjustment for chance in clustering performance evaluation*: Analysis of the impact of the dataset size on the value of clustering measures for random assignments.

## Mathematical formulation

If  $C$  is a ground truth class assignment and  $K$  the clustering, let us define  $a$  and  $b$  as:

- $a$ , the number of pairs of elements that are in the same set in  $C$  and in the same set in  $K$
- $b$ , the number of pairs of elements that are in different sets in  $C$  and in different sets in  $K$

The raw (unadjusted) Rand index is then given by:

$$\text{RI} = \frac{a + b}{C_2^{n_{samples}}}$$

Where  $C_2^{n_{samples}}$  is the total number of possible pairs in the dataset (without ordering).

However the RI score does not guarantee that random label assignments will get a value close to zero (esp. if the number of clusters is in the same order of magnitude as the number of samples).

To counter this effect we can discount the expected RI  $E[\text{RI}]$  of random labelings by defining the adjusted Rand index as follows:

$$\text{ARI} = \frac{\text{RI} - E[\text{RI}]}{\max(\text{RI}) - E[\text{RI}]}$$

## References

- Comparing Partitions L. Hubert and P. Arabie, Journal of Classification 1985

## Mutual Information based scores

Given the knowledge of the ground truth class assignments `labels_true` and our clustering algorithm assignments of the same samples `labels_pred`, the **Mutual Information** is a function that measures the **agreement** of the two assignments, ignoring permutations. Two different normalized versions of this measure are available, **Normalized Mutual Information(NMI)** and **Adjusted Mutual Information(AMI)**. NMI is often used in the literature while AMI was proposed more recently and is **normalized against chance**:

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
0.22504...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3 and get the same score:

```
>>> labels_pred = [1, 1, 0, 0, 3, 3]
>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
0.22504...
```

All, `mutual_info_score`, `adjusted_mutual_info_score` and `normalized_mutual_info_score` are symmetric: swapping the argument does not change the score. Thus they can be used as a **consensus measure**:

```
>>> metrics.adjusted_mutual_info_score(labels_pred, labels_true)
0.22504...
```

Perfect labeling is scored 1.0:

```
>>> labels_pred = labels_true[:]
>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
1.0

>>> metrics.normalized_mutual_info_score(labels_true, labels_pred)
1.0
```

This is not true for `mutual_info_score`, which is therefore harder to judge:

```
>>> metrics.mutual_info_score(labels_true, labels_pred)
0.69...
```

Bad (e.g. independent labelings) have non-positive scores:

```
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]
>>> metrics.adjusted_mutual_info_score(labels_true, labels_pred)
-0.10526...
```

## Advantages

- **Random (uniform) label assignments have a AMI score close to 0.0** for any value of `n_clusters` and `n_samples` (which is not the case for raw Mutual Information or the V-measure for instance).
- **Bounded range [0, 1]**: Values close to zero indicate two label assignments that are largely independent, while values close to one indicate significant agreement. Further, values of exactly 0 indicate **purely** independent label assignments and a AMI of exactly 1 indicates that the two label assignments are equal (with or without permutation).
- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes.

## Drawbacks

- Contrary to inertia, **MI-based measures require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

However MI-based measures can also be useful in purely unsupervised setting as a building block for a Consensus Index that can be used for clustering model selection.

- NMI and MI are not adjusted against chance.

### Examples:

- *Adjustment for chance in clustering performance evaluation*: Analysis of the impact of the dataset size on the value of clustering measures for random assignments. This example also includes the Adjusted Rand Index.

## Mathematical formulation

Assume two label assignments (of the same  $N$  objects),  $U$  and  $V$ . Their entropy is the amount of uncertainty for a partition set, defined by:

$$H(U) = \sum_{i=1}^{|U|} P(i) \log(P(i))$$

where  $P(i) = |U_i|/N$  is the probability that an object picked at random from  $U$  falls into class  $U_i$ . Likewise for  $V$ :

$$H(V) = \sum_{j=1}^{|V|} P'(j) \log(P'(j))$$

With  $P'(j) = |V_j|/N$ . The mutual information (MI) between  $U$  and  $V$  is calculated by:

$$\text{MI}(U, V) = \sum_{i=1}^{|U|} \sum_{j=1}^{|V|} P(i, j) \log \left( \frac{P(i, j)}{P(i)P'(j)} \right)$$

where  $P(i, j) = |U_i \cap V_j|/N$  is the probability that an object picked at random falls into both classes  $U_i$  and  $V_j$ .

It also can be expressed in set cardinality formulation:

$$\text{MI}(U, V) = \sum_{i=1}^{|U|} |U_i| \sum_{j=1}^{|V|} |V_j| \frac{|U_i \cap V_j|}{N} \log \left( \frac{N|U_i \cap V_j|}{|U_i||V_j|} \right)$$

The normalized mutual information is defined as

$$\text{NMI}(U, V) = \frac{\text{MI}(U, V)}{\sqrt{H(U)H(V)}}$$

This value of the mutual information and also the normalized variant is not adjusted for chance and will tend to increase as the number of different labels (clusters) increases, regardless of the actual amount of “mutual information” between the label assignments.

The expected value for the mutual information can be calculated using the following equation, from Vinh, Epps, and Bailey, (2009). In this equation,  $a_i = |U_i|$  (the number of elements in  $U_i$ ) and  $b_j = |V_j|$  (the number of elements in  $V_j$ ).

$$E[\text{MI}(U, V)] = \sum_{i=1}^{|U|} |U_i| \sum_{j=1}^{|V|} |V_j| \sum_{n_{ij}=(a_i+b_j-N)^+}^{\min(a_i, b_j)} \frac{n_{ij}}{N} \log \left( \frac{N \cdot n_{ij}}{a_i b_j} \right) \frac{a_i! b_j! (N - a_i)! (N - b_j)!}{N! n_{ij}! (a_i - n_{ij})! (b_j - n_{ij})! (N - a_i - b_j + n_{ij})!}$$

Using the expected value, the adjusted mutual information can then be calculated using a similar form to that of the adjusted Rand index:

$$\text{AMI} = \frac{\text{MI} - E[\text{MI}]}{\max(H(U), H(V)) - E[\text{MI}]}$$

## Homogeneity, completeness and V-measure

Given the knowledge of the ground truth class assignments of the samples, it is possible to define some intuitive metric using conditional entropy analysis.

In particular Rosenberg and Hirschberg (2007) define the following two desirable objectives for any cluster assignment:

- **homogeneity**: each cluster contains only members of a single class.
- **completeness**: all members of a given class are assigned to the same cluster.

We can turn those concept as scores `homogeneity_score` and `completeness_score`. Both are bounded below by 0.0 and above by 1.0 (higher is better):

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]

>>> metrics.homogeneity_score(labels_true, labels_pred)
0.66...

>>> metrics.completeness_score(labels_true, labels_pred)
0.42...
```

Their harmonic mean called **V-measure** is computed by `v_measure_score`:

```
>>> metrics.v_measure_score(labels_true, labels_pred)
0.51...
```

The V-measure is actually equivalent to the mutual information (NMI) discussed above normalized by the sum of the label entropies [\[B2011\]](#).

Homogeneity, completeness and V-measure can be computed at once using `homogeneity_completeness_v_measure` as follows:

```
>>> metrics.homogeneity_completeness_v_measure(labels_true, labels_pred)
...
(0.66..., 0.42..., 0.51...)
```

The following clustering assignment is slightly better, since it is homogeneous but not complete:

```
>>> labels_pred = [0, 0, 0, 1, 2, 2]
>>> metrics.homogeneity_completeness_v_measure(labels_true, labels_pred)
...
(1.0, 0.68..., 0.81...)
```

---

**Note:** `v_measure_score` is **symmetric**: it can be used to evaluate the **agreement** of two independent assignments on the same dataset.

This is not the case for `completeness_score` and `homogeneity_score`: both are bound by the relationship:

```
homogeneity_score(a, b) == completeness_score(b, a)
```

---

## Advantages

- **Bounded scores:** 0.0 is as bad as it can be, 1.0 is a perfect score.
- Intuitive interpretation: clustering with bad V-measure can be **qualitatively analyzed in terms of homogeneity and completeness** to better feel what ‘kind’ of mistakes is done by the assignment.
- **No assumption is made on the cluster structure:** can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes.

## Drawbacks

- The previously introduced metrics are **not normalized with regards to random labeling**: this means that depending on the number of samples, clusters and ground truth classes, a completely random labeling will not always yield the same values for homogeneity, completeness and hence v-measure. In particular **random labeling won’t yield zero scores especially when the number of clusters is large**.

This problem can safely be ignored when the number of samples is more than a thousand and the number of clusters is less than 10. **For smaller sample sizes or larger number of clusters it is safer to use an adjusted index such as the Adjusted Rand Index (ARI).**

- These metrics **require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

### Examples:

- *Adjustment for chance in clustering performance evaluation:* Analysis of the impact of the dataset size on the value of clustering measures for random assignments.

## Mathematical formulation

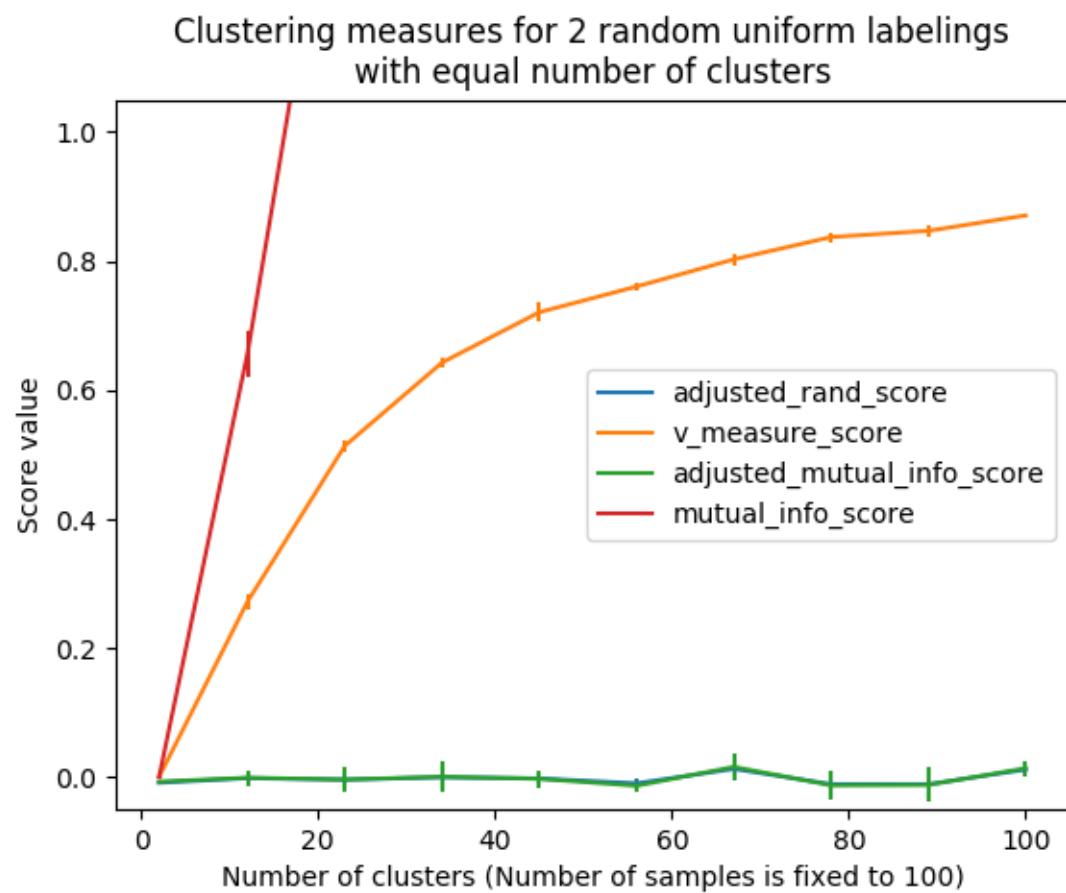

Homogeneity and completeness scores are formally given by:

$$h = 1 - \frac{H(C|K)}{H(C)}$$

$$c = 1 - \frac{H(K|C)}{H(K)}$$

where  $H(C|K)$  is the **conditional entropy of the classes given the cluster assignments** and is given by:

$$H(C|K) = - \sum_{c=1}^{|C|} \sum_{k=1}^{|K|} \frac{n_{c,k}}{n} \cdot \log \left( \frac{n_{c,k}}{n_k} \right)$$

and  $H(C)$  is the **entropy of the classes** and is given by:

$$H(C) = - \sum_{c=1}^{|C|} \frac{n_c}{n} \cdot \log\left(\frac{n_c}{n}\right)$$

with  $n$  the total number of samples,  $n_c$  and  $n_k$  the number of samples respectively belonging to class  $c$  and cluster  $k$ , and finally  $n_{c,k}$  the number of samples from class  $c$  assigned to cluster  $k$ .

The **conditional entropy of clusters given class**  $H(K|C)$  and the **entropy of clusters**  $H(K)$  are defined in a symmetric manner.

Rosenberg and Hirschberg further define **V-measure** as the **harmonic mean of homogeneity and completeness**:

$$v = 2 \cdot \frac{h \cdot c}{h + c}$$

## References

### Fowlkes-Mallows scores

The Fowlkes-Mallows index (`sklearn.metrics.fowlkes_mallows_score`) can be used when the ground truth class assignments of the samples is known. The Fowlkes-Mallows score FMI is defined as the geometric mean of the pairwise precision and recall:

$$\text{FMI} = \frac{\text{TP}}{\sqrt{(\text{TP} + \text{FP})(\text{TP} + \text{FN})}}$$

Where TP is the number of **True Positive** (i.e. the number of pair of points that belong to the same clusters in both the true labels and the predicted labels), FP is the number of **False Positive** (i.e. the number of pair of points that belong to the same clusters in the true labels and not in the predicted labels) and FN is the number of **False Negative** (i.e. the number of pair of points that belongs in the same clusters in the predicted labels and not in the true labels).

The score ranges from 0 to 1. A high value indicates a good similarity between two clusters.

```
>>> from sklearn import metrics
>>> labels_true = [0, 0, 0, 1, 1, 1]
>>> labels_pred = [0, 0, 1, 1, 2, 2]
```

```
>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.47140...
```

One can permute 0 and 1 in the predicted labels, rename 2 to 3 and get the same score:

```
>>> labels_pred = [1, 1, 0, 0, 3, 3]
>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.47140...
```

Perfect labeling is scored 1.0:

```
>>> labels_pred = labels_true[:]
>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
1.0
```

Bad (e.g. independent labelings) have zero scores:

```
>>> labels_true = [0, 1, 2, 0, 3, 4, 5, 1]
>>> labels_pred = [1, 1, 0, 0, 2, 2, 2, 2]
>>> metrics.fowlkes_mallows_score(labels_true, labels_pred)
0.0
```

## Advantages

- **Random (uniform) label assignments have a FMI score close to 0.0** for any value of `n_clusters` and `n_samples` (which is not the case for raw Mutual Information or the V-measure for instance).
- **Bounded range [0, 1]**: Values close to zero indicate two label assignments that are largely independent, while values close to one indicate significant agreement. Further, values of exactly 0 indicate **purely** independent label assignments and a AMI of exactly 1 indicates that the two label assignments are equal (with or without permutation).
- **No assumption is made on the cluster structure**: can be used to compare clustering algorithms such as k-means which assumes isotropic blob shapes with results of spectral clustering algorithms which can find cluster with “folded” shapes.

## Drawbacks

- Contrary to inertia, **FMI-based measures require the knowledge of the ground truth classes** while almost never available in practice or requires manual assignment by human annotators (as in the supervised learning setting).

## Silhouette Coefficient

If the ground truth labels are not known, evaluation must be performed using the model itself. The Silhouette Coefficient (`sklearn.metrics.silhouette_score`) is an example of such an evaluation, where a higher Silhouette Coefficient score relates to a model with better defined clusters. The Silhouette Coefficient is defined for each sample and is composed of two scores:

- **a**: The mean distance between a sample and all other points in the same class.
- **b**: The mean distance between a sample and all other points in the *next nearest cluster*.

The Silhouette Coefficient  $s$  for a single sample is then given as:

$$s = \frac{b - a}{\max(a, b)}$$

The Silhouette Coefficient for a set of samples is given as the mean of the Silhouette Coefficient for each sample.

```
>>> from sklearn import metrics
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn import datasets
```

```
>>> dataset = datasets.load_iris()
>>> X = dataset.data
>>> y = dataset.target
```

In normal usage, the Silhouette Coefficient is applied to the results of a cluster analysis.

```
>>> import numpy as np
>>> from sklearn.cluster import KMeans
>>> kmeans_model = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans_model.labels_
>>> metrics.silhouette_score(X, labels, metric='euclidean')
...
0.55...
```

## References

- Peter J. Rousseeuw (1987). “Silhouettes: a Graphical Aid to the Interpretation and Validation of Cluster Analysis”. Computational and Applied Mathematics 20: 53–65. doi:10.1016/0377-0427(87)90125-7.

## Advantages

- The score is bounded between -1 for incorrect clustering and +1 for highly dense clustering. Scores around zero indicate overlapping clusters.
- The score is higher when clusters are dense and well separated, which relates to a standard concept of a cluster.

## Drawbacks

- The Silhouette Coefficient is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained through DBSCAN.

## Examples:

- *Selecting the number of clusters with silhouette analysis on KMeans clustering* : In this example the silhouette analysis is used to choose an optimal value for n\_clusters.

## Calinski-Harabaz Index

If the ground truth labels are not known, the Calinski-Harabaz index (`sklearn.metrics.calinski_harabaz_score`) can be used to evaluate the model, where a higher Calinski-Harabaz score relates to a model with better defined clusters.

For  $k$  clusters, the Calinski-Harabaz score  $s$  is given as the ratio of the between-clusters dispersion mean and the within-cluster dispersion:

$$s(k) = \frac{\text{Tr}(B_k)}{\text{Tr}(W_k)} \times \frac{N - k}{k - 1}$$

where  $B_K$  is the between group dispersion matrix and  $W_K$  is the within-cluster dispersion matrix defined by:

$$W_k = \sum_{q=1}^k \sum_{x \in C_q} (x - c_q)(x - c_q)^T$$

$$B_k = \sum_q n_q (c_q - c)(c_q - c)^T$$

with  $N$  be the number of points in our data,  $C_q$  be the set of points in cluster  $q$ ,  $c_q$  be the center of cluster  $q$ ,  $c$  be the center of  $E$ ,  $n_q$  be the number of points in cluster  $q$ .

```
>>> from sklearn import metrics
>>> from sklearn.metrics import pairwise_distances
>>> from sklearn import datasets
>>> dataset = datasets.load_iris()
>>> X = dataset.data
>>> y = dataset.target
```

In normal usage, the Calinski-Harabaz index is applied to the results of a cluster analysis.

```
>>> import numpy as np
>>> from sklearn.cluster import KMeans
>>> kmeans_model = KMeans(n_clusters=3, random_state=1).fit(X)
>>> labels = kmeans_model.labels_
>>> metrics.calinski_harabaz_score(X, labels)
560.39...
```

## Advantages

- The score is higher when clusters are dense and well separated, which relates to a standard concept of a cluster.
- The score is fast to compute

## Drawbacks

- The Calinski-Harabaz index is generally higher for convex clusters than other concepts of clusters, such as density based clusters like those obtained through DBSCAN.

## 3.2.4 Biclustering

Biclustering can be performed with the module `sklearn.cluster.bicluster`. Biclustering algorithms simultaneously cluster rows and columns of a data matrix. These clusters of rows and columns are known as biclusters. Each determines a submatrix of the original data matrix with some desired properties.

For instance, given a matrix of shape (10, 10), one possible bicluster with three rows and two columns induces a submatrix of shape (3, 2):

```
>>> import numpy as np
>>> data = np.arange(100).reshape(10, 10)
>>> rows = np.array([0, 2, 3])[:, np.newaxis]
>>> columns = np.array([1, 2])
>>> data[rows, columns]
array([[ 1,  2],
       [21, 22],
       [31, 32]])
```

For visualization purposes, given a bicluster, the rows and columns of the data matrix may be rearranged to make the bicluster contiguous.

Algorithms differ in how they define biclusters. Some of the common types include:

- constant values, constant rows, or constant columns
- unusually high or low values
- submatrices with low variance
- correlated rows or columns

Algorithms also differ in how rows and columns may be assigned to biclusters, which leads to different bicluster structures. Block diagonal or checkerboard structures occur when rows and columns are divided into partitions.

If each row and each column belongs to exactly one bicluster, then rearranging the rows and columns of the data matrix reveals the biclusters on the diagonal. Here is an example of this structure where biclusters have higher average values than the other rows and columns:

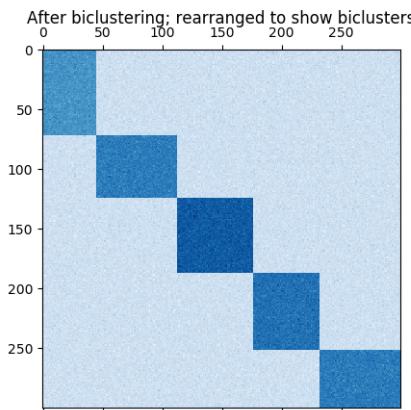

Fig. 3.5: An example of biclusters formed by partitioning rows and columns.

In the checkerboard case, each row belongs to all column clusters, and each column belongs to all row clusters. Here is an example of this structure where the variance of the values within each bicluster is small:

After fitting a model, row and column cluster membership can be found in the `rows_` and `columns_` attributes. `rows_[i]` is a binary vector with nonzero entries corresponding to rows that belong to bicluster `i`. Similarly, `columns_[i]` indicates which columns belong to bicluster `i`.

Some models also have `row_labels_` and `column_labels_` attributes. These models partition the rows and columns, such as in the block diagonal and checkerboard bicluster structures.

---

**Note:** Biclustering has many other names in different fields including co-clustering, two-mode clustering, two-way

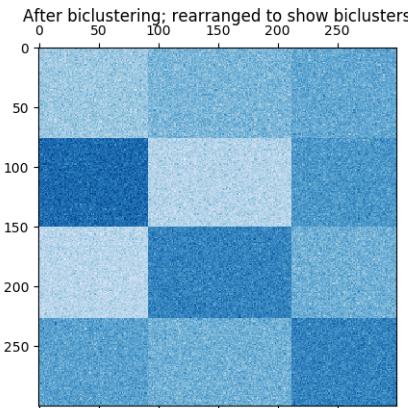

Fig. 3.6: An example of checkerboard biclusters.

clustering, block clustering, coupled two-way clustering, etc. The names of some algorithms, such as the Spectral Co-Clustering algorithm, reflect these alternate names.

## Spectral Co-Clustering

The *SpectralCoclustering* algorithm finds biclusters with values higher than those in the corresponding other rows and columns. Each row and each column belongs to exactly one bicluster, so rearranging the rows and columns to make partitions contiguous reveals these high values along the diagonal:

---

**Note:** The algorithm treats the input data matrix as a bipartite graph: the rows and columns of the matrix correspond to the two sets of vertices, and each entry corresponds to an edge between a row and a column. The algorithm approximates the normalized cut of this graph to find heavy subgraphs.

---

## Mathematical formulation

An approximate solution to the optimal normalized cut may be found via the generalized eigenvalue decomposition of the Laplacian of the graph. Usually this would mean working directly with the Laplacian matrix. If the original data matrix  $A$  has shape  $m \times n$ , the Laplacian matrix for the corresponding bipartite graph has shape  $(m+n) \times (m+n)$ . However, in this case it is possible to work directly with  $A$ , which is smaller and more efficient.

The input matrix  $A$  is preprocessed as follows:

$$A_n = R^{-1/2} A C^{-1/2}$$

Where  $R$  is the diagonal matrix with entry  $i$  equal to  $\sum_j A_{ij}$  and  $C$  is the diagonal matrix with entry  $j$  equal to  $\sum_i A_{ij}$ .

The singular value decomposition,  $A_n = U \Sigma V^\top$ , provides the partitions of the rows and columns of  $A$ . A subset of the left singular vectors gives the row partitions, and a subset of the right singular vectors gives the column partitions.

The  $\ell = \lceil \log_2 k \rceil$  singular vectors, starting from the second, provide the desired partitioning information. They are

used to form the matrix  $Z$ :

$$Z = \begin{bmatrix} R^{-1/2}U \\ C^{-1/2}V \end{bmatrix}$$

where the columns of  $U$  are  $u_2, \dots, u_{\ell+1}$ , and similarly for  $V$ .

Then the rows of  $Z$  are clustered using [k-means](#). The first `n_rows` labels provide the row partitioning, and the remaining `n_columns` labels provide the column partitioning.

### Examples:

- [A demo of the Spectral Co-Clustering algorithm](#): A simple example showing how to generate a data matrix with biclusters and apply this method to it.
- `sphx_glr_auto_examples_bicluster_bicluster_newsgroups.py`: An example of finding biclusters in the twenty newsgroup dataset.

### References:

- Dhillon, Inderjit S, 2001. [Co-clustering documents and words using bipartite spectral graph partitioning](#).

## Spectral Biclustering

The [SpectralBiclustering](#) algorithm assumes that the input data matrix has a hidden checkerboard structure. The rows and columns of a matrix with this structure may be partitioned so that the entries of any bicluster in the Cartesian product of row clusters and column clusters are approximately constant. For instance, if there are two row partitions and three column partitions, each row will belong to three biclusters, and each column will belong to two biclusters.

The algorithm partitions the rows and columns of a matrix so that a corresponding blockwise-constant checkerboard matrix provides a good approximation to the original matrix.

## Mathematical formulation

The input matrix  $A$  is first normalized to make the checkerboard pattern more obvious. There are three possible methods:

1. *Independent row and column normalization*, as in Spectral Co-Clustering. This method makes the rows sum to a constant and the columns sum to a different constant.
2. **Bistochasticization**: repeated row and column normalization until convergence. This method makes both rows and columns sum to the same constant.
3. **Log normalization**: the log of the data matrix is computed:  $L = \log A$ . Then the column mean  $\overline{L}_{\cdot i}$ , row mean  $\overline{L}_{\cdot j}$ , and overall mean  $\overline{L}_{..}$  of  $L$  are computed. The final matrix is computed according to the formula

$$K_{ij} = L_{ij} - \overline{L}_{\cdot i} - \overline{L}_{\cdot j} + \overline{L}_{..}$$

After normalizing, the first few singular vectors are computed, just as in the Spectral Co-Clustering algorithm.

If log normalization was used, all the singular vectors are meaningful. However, if independent normalization or bistochasticization were used, the first singular vectors,  $u_1$  and  $v_1$ , are discarded. From now on, the “first” singular vectors refers to  $u_2 \dots u_{p+1}$  and  $v_2 \dots v_{p+1}$  except in the case of log normalization.

Given these singular vectors, they are ranked according to which can be best approximated by a piecewise-constant vector. The approximations for each vector are found using one-dimensional k-means and scored using the Euclidean distance. Some subset of the best left and right singular vector are selected. Next, the data is projected to this best subset of singular vectors and clustered.

For instance, if  $p$  singular vectors were calculated, the  $q$  best are found as described, where  $q < p$ . Let  $U$  be the matrix with columns the  $q$  best left singular vectors, and similarly  $V$  for the right. To partition the rows, the rows of  $A$  are projected to a  $q$  dimensional space:  $A * V$ . Treating the  $m$  rows of this  $m \times q$  matrix as samples and clustering using k-means yields the row labels. Similarly, projecting the columns to  $A^\top * U$  and clustering this  $n \times q$  matrix yields the column labels.

## Biclustering evaluation

There are two ways of evaluating a biclustering result: internal and external. Internal measures, such as cluster stability, rely only on the data and the result themselves. Currently there are no internal bicluster measures in scikit-learn. External measures refer to an external source of information, such as the true solution. When working with real data the true solution is usually unknown, but biclustering artificial data may be useful for evaluating algorithms precisely because the true solution is known.

To compare a set of found biclusters to the set of true biclusters, two similarity measures are needed: a similarity measure for individual biclusters, and a way to combine these individual similarities into an overall score.

To compare individual biclusters, several measures have been used. For now, only the Jaccard index is implemented:

$$J(A, B) = \frac{|A \cap B|}{|A| + |B| - |A \cap B|}$$

where  $A$  and  $B$  are biclusters,  $|A \cap B|$  is the number of elements in their intersection. The Jaccard index achieves its minimum of 0 when the biclusters to not overlap at all and its maximum of 1 when they are identical.

Several methods have been developed to compare two sets of biclusters. For now, only `consensus_score` (Hochreiter et. al., 2010) is available:

1. Compute bicluster similarities for pairs of biclusters, one in each set, using the Jaccard index or a similar measure.
2. Assign biclusters from one set to another in a one-to-one fashion to maximize the sum of their similarities. This step is performed using the Hungarian algorithm.
3. The final sum of similarities is divided by the size of the larger set.

The minimum consensus score, 0, occurs when all pairs of biclusters are totally dissimilar. The maximum score, 1, occurs when both sets are identical.

### 3.2.5 Decomposing signals in components (matrix factorization problems)

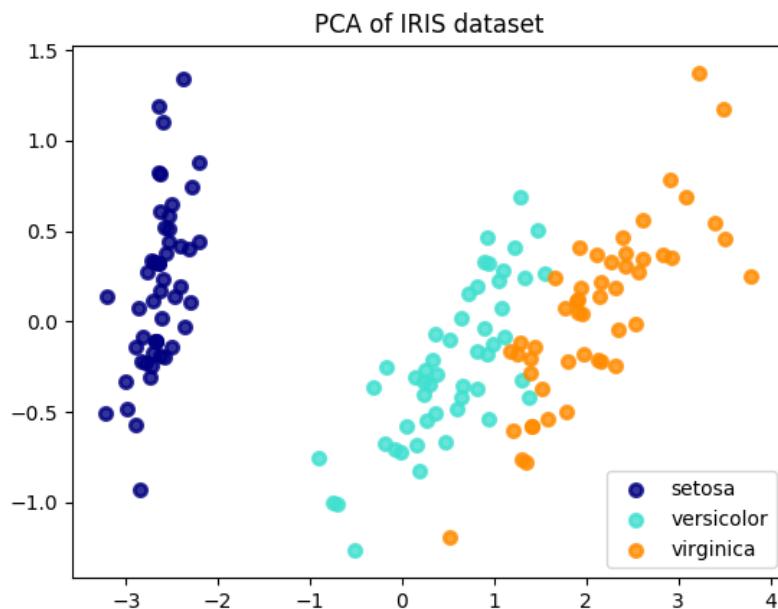

#### Principal component analysis (PCA)

##### Exact PCA and probabilistic interpretation

PCA is used to decompose a multivariate dataset in a set of successive orthogonal components that explain a maximum amount of the variance. In scikit-learn, `PCA` is implemented as a *transformer* object that learns  $n$  components in its `fit` method, and can be used on new data to project it on these components.

The optional parameter `whiten=True` makes it possible to project the data onto the singular space while scaling each component to unit variance. This is often useful if the models down-stream make strong assumptions on the isotropy of the signal: this is for example the case for Support Vector Machines with the RBF kernel and the K-Means clustering algorithm.

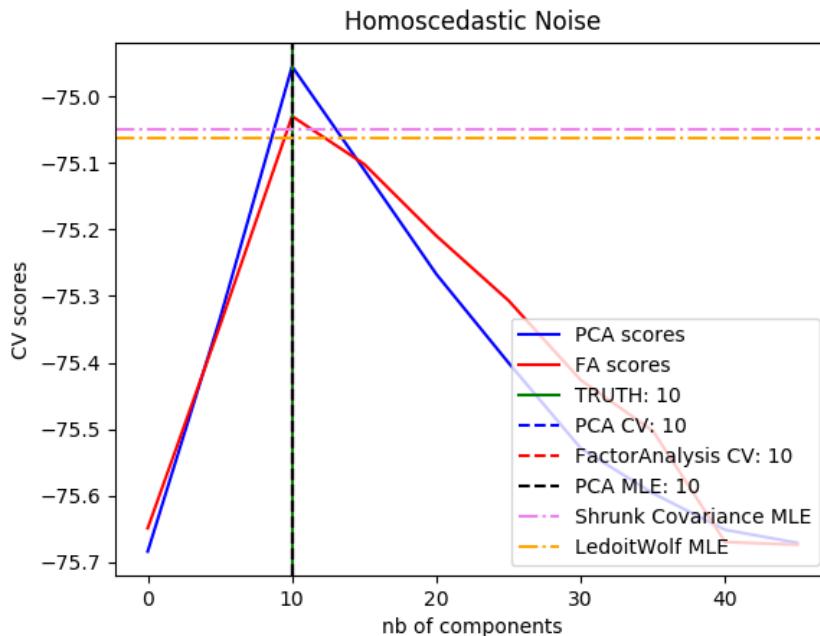

Below is an example of the iris dataset, which is comprised of 4 features, projected on the 2 dimensions that explain most variance:

The `PCA` object also provides a probabilistic interpretation of the PCA that can give a likelihood of data based on the amount of variance it explains. As such it implements a `score` method that can be used in cross-validation:

**Examples:**

- *Comparison of LDA and PCA 2D projection of Iris dataset*

- Model selection with Probabilistic PCA and Factor Analysis (FA)

## Incremental PCA

The `PCA` object is very useful, but has certain limitations for large datasets. The biggest limitation is that `PCA` only supports batch processing, which means all of the data to be processed must fit in main memory. The `IncrementalPCA` object uses a different form of processing and allows for partial computations which almost exactly match the results of `PCA` while processing the data in a minibatch fashion. `IncrementalPCA` makes it possible to implement out-of-core Principal Component Analysis either by:

- Using its `partial_fit` method on chunks of data fetched sequentially from the local hard drive or a network database.
- Calling its `fit` method on a memory mapped file using `numpy.memmap`.

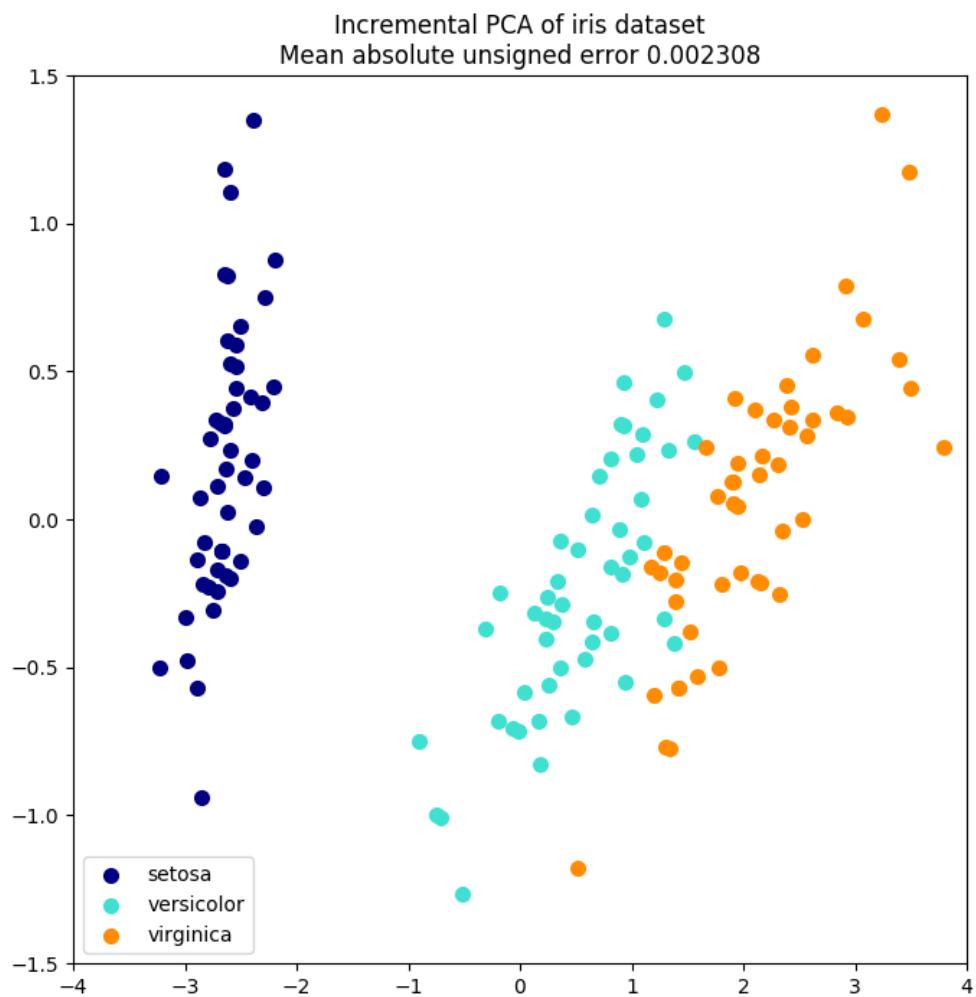

`IncrementalPCA` only stores estimates of component and noise variances, in order update `explained_variance_ratio_` incrementally. This is why memory usage depends on the number of samples per batch, rather than the number of samples to be processed in the dataset.

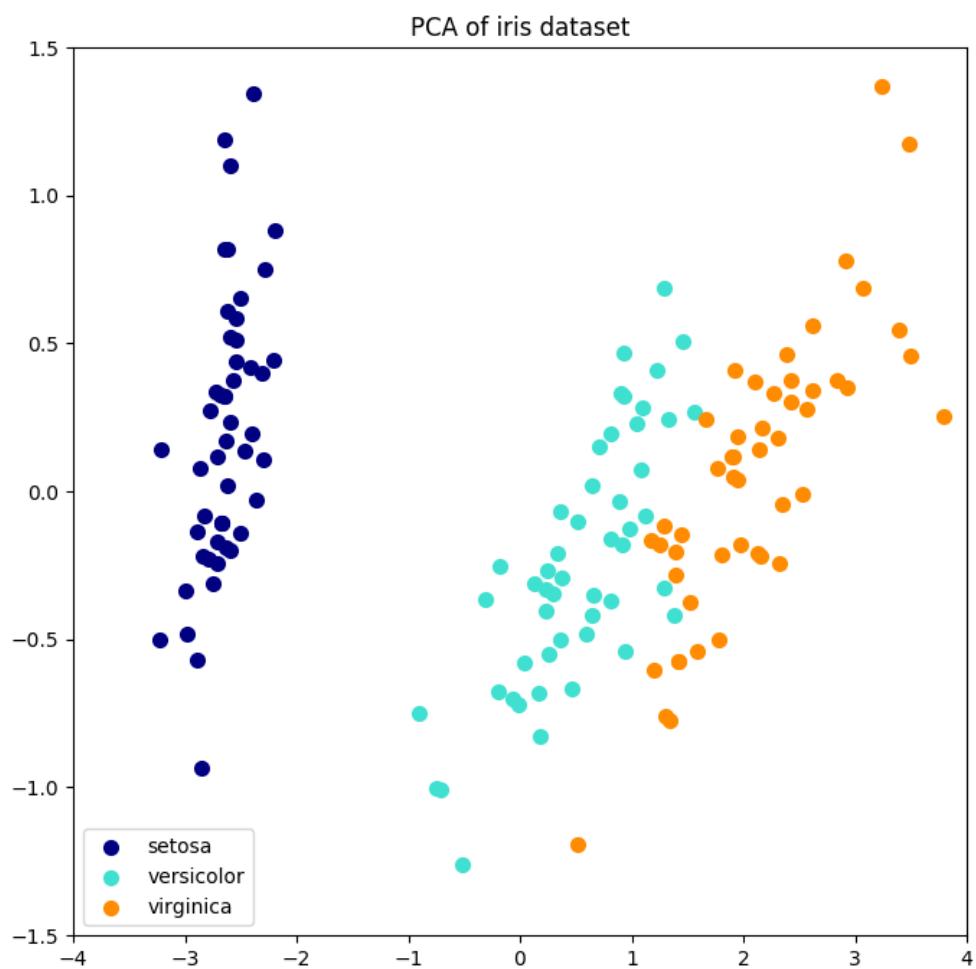

### Examples:

- Incremental PCA

## PCA using randomized SVD

It is often interesting to project data to a lower-dimensional space that preserves most of the variance, by dropping the singular vector of components associated with lower singular values.

For instance, if we work with 64x64 pixel gray-level pictures for face recognition, the dimensionality of the data is 4096 and it is slow to train an RBF support vector machine on such wide data. Furthermore we know that the intrinsic dimensionality of the data is much lower than 4096 since all pictures of human faces look somewhat alike. The samples lie on a manifold of much lower dimension (say around 200 for instance). The PCA algorithm can be used to linearly transform the data while both reducing the dimensionality and preserve most of the explained variance at the same time.

The class `PCA` used with the optional parameter `svd_solver='randomized'` is very useful in that case: since we are going to drop most of the singular vectors it is much more efficient to limit the computation to an approximated estimate of the singular vectors we will keep to actually perform the transform.

For instance, the following shows 16 sample portraits (centered around 0.0) from the Olivetti dataset. On the right hand side are the first 16 singular vectors reshaped as portraits. Since we only require the top 16 singular vectors of a dataset with size  $n_{samples} = 400$  and  $n_{features} = 64 \times 64 = 4096$ , the computation time is less than 1s:

Note: with the optional parameter `svd_solver='randomized'`, we also need to give `PCA` the size of the lower-dimensional space `n_components` as a mandatory input parameter.

If we note  $n_{\max} = \max(n_{samples}, n_{features})$  and  $n_{\min} = \min(n_{samples}, n_{features})$ , the time complexity of the randomized `PCA` is  $O(n_{\max}^2 \cdot n_{components})$  instead of  $O(n_{\max}^2 \cdot n_{\min})$  for the exact method implemented in `PCA`.

The memory footprint of randomized `PCA` is also proportional to  $2 \cdot n_{\max} \cdot n_{components}$  instead of  $n_{\max} \cdot n_{\min}$  for the exact method.

Note: the implementation of `inverse_transform` in `PCA` with `svd_solver='randomized'` is not the exact inverse transform of `transform` even when `whiten=False` (default).

- `sphx_glr_auto_examples_applications_face_recognition.py`
- `Faces dataset decompositions`

### References:

- “Finding structure with randomness: Stochastic algorithms for constructing approximate matrix decompositions” Halko, et al., 2009

## Kernel PCA

`KernelPCA` is an extension of PCA which achieves non-linear dimensionality reduction through the use of kernels (see [Pairwise metrics, Affinities and Kernels](#)). It has many applications including denoising, compression and structured prediction (kernel dependency estimation). `KernelPCA` supports both `transform` and `inverse_transform`.

### Examples:

- `Kernel PCA`

## Sparse principal components analysis (SparsePCA and MiniBatchSparsePCA)

*SparsePCA* is a variant of PCA, with the goal of extracting the set of sparse components that best reconstruct the data.

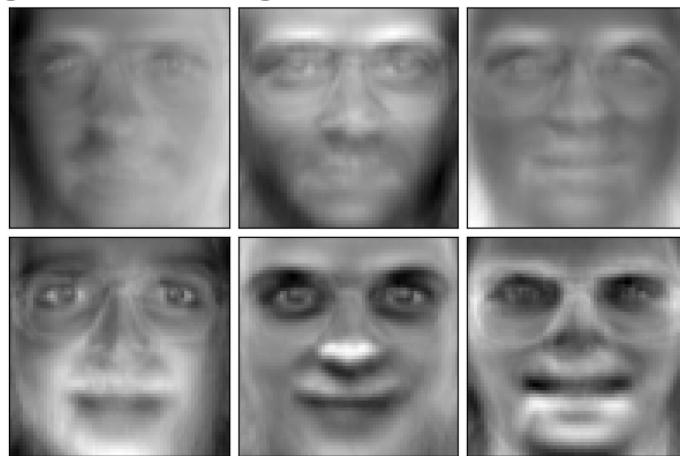

Mini-batch sparse PCA (*MiniBatchSparsePCA*) is a variant of *SparsePCA* that is faster but less accurate. The increased speed is reached by iterating over small chunks of the set of features, for a given number of iterations.

Principal component analysis (*PCA*) has the disadvantage that the components extracted by this method have exclusively dense expressions, i.e. they have non-zero coefficients when expressed as linear combinations of the original variables. This can make interpretation difficult. In many cases, the real underlying components can be more naturally imagined as sparse vectors; for example in face recognition, components might naturally map to parts of faces.

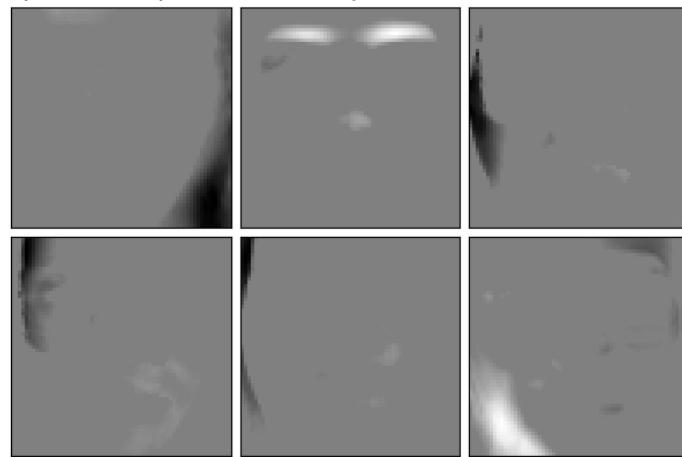

Sparse principal components yields a more parsimonious, interpretable representation, clearly emphasizing which of the original features contribute to the differences between samples.

The following example illustrates 16 components extracted using sparse PCA from the Olivetti faces dataset. It can be seen how the regularization term induces many zeros. Furthermore, the natural structure of the data causes the non-zero coefficients to be vertically adjacent. The model does not enforce this mathematically: each component is a vector  $h \in \mathbf{R}^{4096}$ , and there is no notion of vertical adjacency except during the human-friendly visualization as 64x64 pixel images. The fact that the components shown below appear local is the effect of the inherent structure of the data, which makes such local patterns minimize reconstruction error. There exist sparsity-inducing norms that take into account adjacency and different kinds of structure; see [\[Jen09\]](#) for a review of such methods. For more details on how to use Sparse PCA, see the Examples section, below.

genfaces - PCA using randomized SVD - Train time 0.1

Sparse comp. - MiniBatchSparsePCA - Train time 1.3s

Note that there are many different formulations for the Sparse PCA problem. The one implemented here is based on [Mr09]. The optimization problem solved is a PCA problem (dictionary learning) with an  $\ell_1$  penalty on the components:

$$(U^*, V^*) = \arg \min_{U, V} \frac{1}{2} \|X - UV\|_2^2 + \alpha \|V\|_1$$

subject to  $\|U_k\|_2 = 1$  for all  $0 \leq k < n_{components}$

The sparsity-inducing  $\ell_1$  norm also prevents learning components from noise when few training samples are available. The degree of penalization (and thus sparsity) can be adjusted through the hyperparameter `alpha`. Small values lead to a gently regularized factorization, while larger values shrink many coefficients to zero.

---

**Note:** While in the spirit of an online algorithm, the class `MiniBatchSparsePCA` does not implement `partial_fit` because the algorithm is online along the features direction, not the samples direction.

---

#### Examples:

- *Faces dataset decompositions*

### Truncated singular value decomposition and latent semantic analysis

`TruncatedSVD` implements a variant of singular value decomposition (SVD) that only computes the  $k$  largest singular values, where  $k$  is a user-specified parameter.

When truncated SVD is applied to term-document matrices (as returned by `CountVectorizer` or `TfidfVectorizer`), this transformation is known as `latent semantic analysis` (LSA), because it transforms such matrices to a “semantic” space of low dimensionality. In particular, LSA is known to combat the effects of synonymy and polysemy (both of which roughly mean there are multiple meanings per word), which cause term-document matrices to be overly sparse and exhibit poor similarity under measures such as cosine similarity.

---

**Note:** LSA is also known as latent semantic indexing, LSI, though strictly that refers to its use in persistent indexes for information retrieval purposes.

---

Mathematically, truncated SVD applied to training samples  $X$  produces a low-rank approximation  $X$ :

$$X \approx X_k = U_k \Sigma_k V_k^\top$$

After this operation,  $U_k \Sigma_k^\top$  is the transformed training set with  $k$  features (called `n_components` in the API).

To also transform a test set  $X$ , we multiply it with  $V_k$ :

$$X' = X V_k$$

---

**Note:** Most treatments of LSA in the natural language processing (NLP) and information retrieval (IR) literature swap the axes of the matrix  $X$  so that it has shape `n_features` × `n_samples`. We present LSA in a different way that matches the scikit-learn API better, but the singular values found are the same.

---

`TruncatedSVD` is very similar to `PCA`, but differs in that it works on sample matrices  $X$  directly instead of their covariance matrices. When the columnwise (per-feature) means of  $X$  are subtracted from the feature values, truncated SVD on the resulting matrix is equivalent to PCA. In practical terms, this means that the `TruncatedSVD` transformer accepts `scipy.sparse` matrices without the need to densify them, as densifying may fill up memory even for medium-sized document collections.

While the `TruncatedSVD` transformer works with any (sparse) feature matrix, using it on tf-idf matrices is recommended over raw frequency counts in an LSA/document processing setting. In particular, sublinear scaling and inverse document frequency should be turned on (`sublinear_tf=True`, `use_idf=True`) to bring the feature values closer to a Gaussian distribution, compensating for LSA's erroneous assumptions about textual data.

### Examples:

- Clustering text documents using `k-means`

## Dictionary Learning

### Sparse coding with a precomputed dictionary

The `SparseCoder` object is an estimator that can be used to transform signals into sparse linear combination of atoms from a fixed, precomputed dictionary such as a discrete wavelet basis. This object therefore does not implement a `fit` method. The transformation amounts to a sparse coding problem: finding a representation of the data as a linear combination of as few dictionary atoms as possible. All variations of dictionary learning implement the following transform methods, controllable via the `transform_method` initialization parameter:

- Orthogonal matching pursuit (*Orthogonal Matching Pursuit (OMP)*)

- Least-angle regression ([Least Angle Regression](#))
- Lasso computed by least-angle regression
- Lasso using coordinate descent ([Lasso](#))
- Thresholding

Thresholding is very fast but it does not yield accurate reconstructions. They have been shown useful in literature for classification tasks. For image reconstruction tasks, orthogonal matching pursuit yields the most accurate, unbiased reconstruction.

The dictionary learning objects offer, via the `split_code` parameter, the possibility to separate the positive and negative values in the results of sparse coding. This is useful when dictionary learning is used for extracting features that will be used for supervised learning, because it allows the learning algorithm to assign different weights to negative loadings of a particular atom, from to the corresponding positive loading.

The split code for a single sample has length  $2 * n\_components$  and is constructed using the following rule: First, the regular code of length `n_components` is computed. Then, the first `n_components` entries of the `split_code` are filled with the positive part of the regular code vector. The second half of the split code is filled with the negative part of the code vector, only with a positive sign. Therefore, the `split_code` is non-negative.

#### Examples:

- [Sparse coding with a precomputed dictionary](#)

### Generic dictionary learning

Dictionary learning ([DictionaryLearning](#)) is a matrix factorization problem that amounts to finding a (usually overcomplete) dictionary that will perform good at sparsely encoding the fitted data.

Representing data as sparse combinations of atoms from an overcomplete dictionary is suggested to be the way the mammal primary visual cortex works. Consequently, dictionary learning applied on image patches has been shown to give good results in image processing tasks such as image completion, inpainting and denoising, as well as for supervised recognition tasks.

Dictionary learning is an optimization problem solved by alternatively updating the sparse code, as a solution to multiple Lasso problems, considering the dictionary fixed, and then updating the dictionary to best fit the sparse code.

$$(U^*, V^*) = \arg \min_{U, V} \frac{1}{2} \|X - UV\|_2^2 + \alpha \|U\|_1$$

subject to  $\|V_k\|_2 = 1$  for all  $0 \leq k < n_{atoms}$

genfaces - PCA using randomized SVD - Train time 0.1

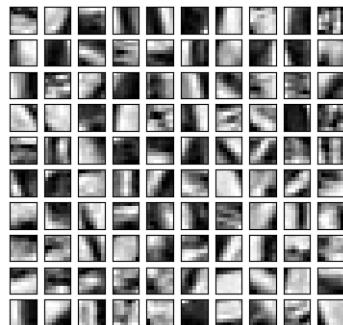

MiniBatchDictionaryLearning - Train time 1.1s

After using such a procedure to fit the dictionary, the transform is simply a sparse coding step that shares the same implementation with all dictionary learning objects (see [Sparse coding with a precomputed dictionary](#)).

The following image shows how a dictionary learned from 4x4 pixel image patches extracted from part of the image of a raccoon face looks like.

Dictionary learned from face patches  
Train time 8.7s on 94500 patches

**Examples:**

- *Image denoising using dictionary learning*

**References:**

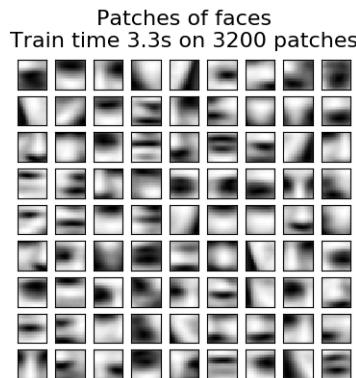

- “Online dictionary learning for sparse coding” J. Mairal, F. Bach, J. Ponce, G. Sapiro, 2009

**Mini-batch dictionary learning**

`MiniBatchDictionaryLearning` implements a faster, but less accurate version of the dictionary learning algorithm that is better suited for large datasets.

By default, `MiniBatchDictionaryLearning` divides the data into mini-batches and optimizes in an online manner by cycling over the mini-batches for the specified number of iterations. However, at the moment it does not implement a stopping condition.

The estimator also implements `partial_fit`, which updates the dictionary by iterating only once over a mini-batch. This can be used for online learning when the data is not readily available from the start, or for when the data does not

fit into the memory.

**Clustering for dictionary learning**

Note that when using dictionary learning to extract a representation (e.g. for sparse coding) clustering can be a good proxy to learn the dictionary. For instance the `MiniBatchKMeans` estimator is computationally efficient and implements on-line learning with a `partial_fit` method.

Example: *Online learning of a dictionary of parts of faces*

**Factor Analysis**

In unsupervised learning we only have a dataset  $X = \{x_1, x_2, \dots, x_n\}$ . How can this dataset be described mathematically? A very simple *continuous latent variable* model for  $X$  is

$$x_i = Wh_i + \mu + \epsilon$$

The vector  $h_i$  is called “latent” because it is unobserved.  $\epsilon$  is considered a noise term distributed according to a Gaussian with mean 0 and covariance  $\Psi$  (i.e.  $\epsilon \sim \mathcal{N}(0, \Psi)$ ),  $\mu$  is some arbitrary offset vector. Such a model is called

“generative” as it describes how  $x_i$  is generated from  $h_i$ . If we use all the  $x_i$ ’s as columns to form a matrix  $\mathbf{X}$  and all the  $h_i$ ’s as columns of a matrix  $\mathbf{H}$  then we can write (with suitably defined  $\mathbf{M}$  and  $\mathbf{E}$ ):

$$\mathbf{X} = \mathbf{W}\mathbf{H} + \mathbf{M} + \mathbf{E}$$

In other words, we *decomposed* matrix  $\mathbf{X}$ .

If  $h_i$  is given, the above equation automatically implies the following probabilistic interpretation:

$$p(x_i|h_i) = \mathcal{N}(W h_i + \mu, \Psi)$$

For a complete probabilistic model we also need a prior distribution for the latent variable  $h$ . The most straightforward assumption (based on the nice properties of the Gaussian distribution) is  $h \sim \mathcal{N}(0, \mathbf{I})$ . This yields a Gaussian as the marginal distribution of  $x$ :

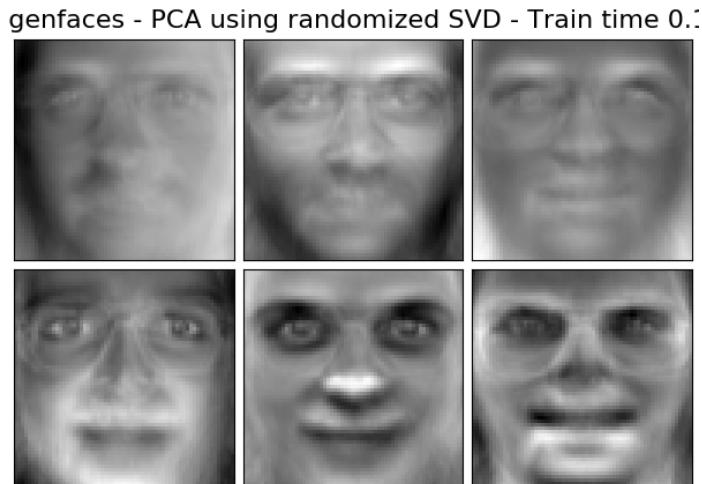

$$p(x) = \mathcal{N}(\mu, W W^T + \Psi)$$

Now, without any further assumptions the idea of having a latent variable  $h$  would be superfluous –  $x$  can be completely modelled with a mean and a covariance. We need to impose some more specific structure on one of these two parameters. A simple additional assumption regards the structure of the error covariance  $\Psi$ :

- $\Psi = \sigma^2 \mathbf{I}$ : This assumption leads to the probabilistic model of [PCA](#).
- $\Psi = \text{diag}(\psi_1, \psi_2, \dots, \psi_n)$ : This model is called [FactorAnalysis](#), a classical statistical model. The matrix  $W$  is sometimes called the “factor loading matrix”.

Both models essentially estimate a Gaussian with a low-rank covariance matrix. Because both models are probabilistic they can be integrated in more complex models, e.g. Mixture of Factor Analysers. One gets very different models (e.g. [FastICA](#)) if non-Gaussian priors on the latent variables are assumed.

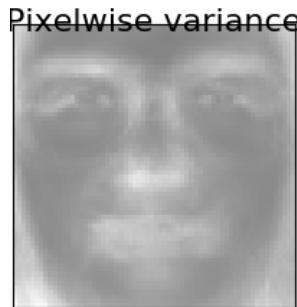

Factor analysis *can* produce similar components (the columns of its loading matrix) to [PCA](#). However, one can not make any general statements about these components (e.g. whether they are orthogonal):

Factor Analysis components - FA - Train time 0.1s

The main advantage for Factor Analysis (over [PCA](#)) is that it can model the variance in every direction of the input space independently (heteroscedastic noise):

This allows better model selection than probabilistic PCA in the presence of heteroscedastic noise:

**Examples:**

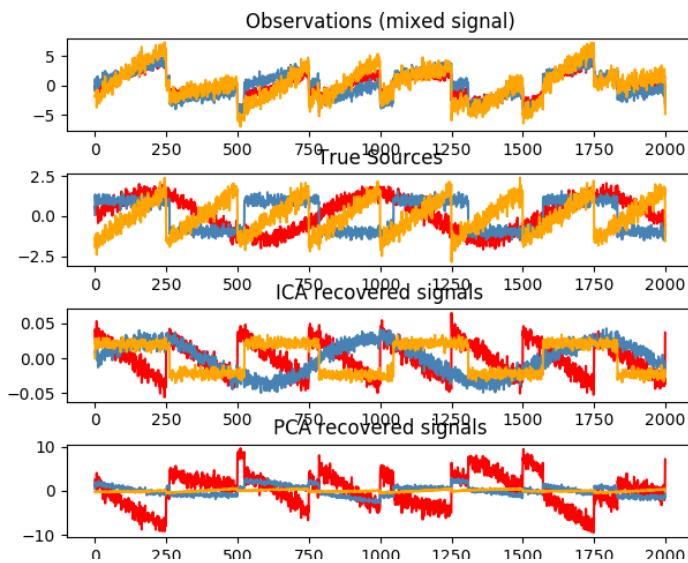

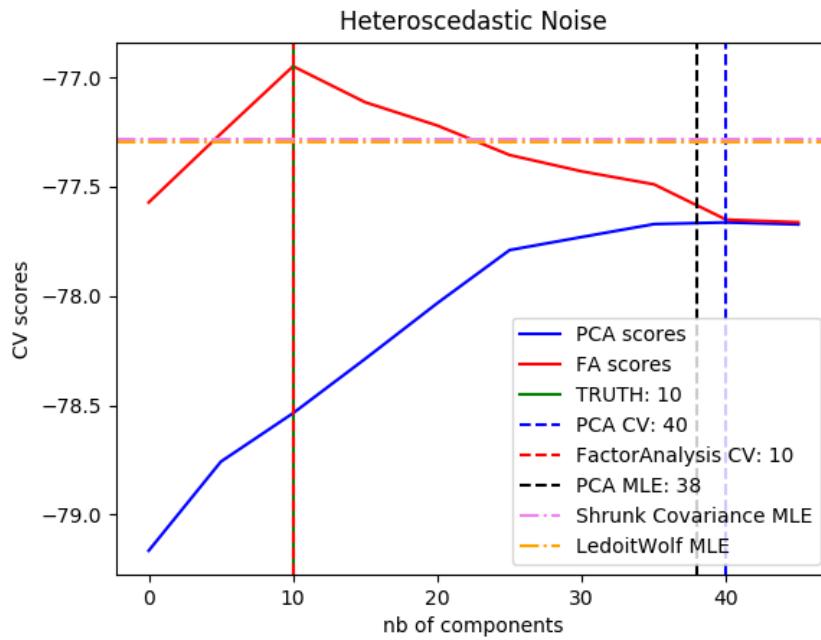

- [Model selection with Probabilistic PCA and Factor Analysis \(FA\)](#)

## Independent component analysis (ICA)

Independent component analysis separates a multivariate signal into additive subcomponents that are maximally independent. It is implemented in scikit-learn using the [Fast ICA](#) algorithm. Typically, ICA is not used for reducing dimensionality but for separating superimposed signals. Since the ICA model does not include a noise term, for the model to be correct, whitening must be applied. This can be done internally using the whiten argument or manually using one of the PCA variants.

It is classically used to separate mixed signals (a problem known as *blind source separation*), as in the example below:

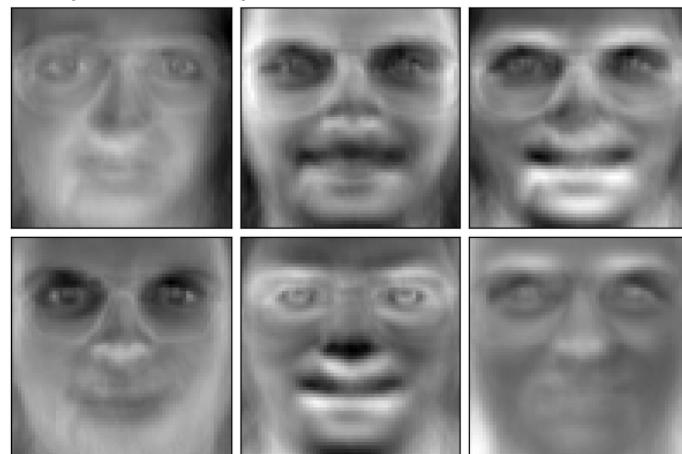

ICA can also be used as yet another non linear decomposition that finds components with some sparsity:

genfaces - PCA using randomized SVD - Train time 0.:

Independent components - FastICA - Train time 0.3s

**Examples:**

- *Blind source separation using FastICA*
- *FastICA on 2D point clouds*
- *Faces dataset decompositions*

**Non-negative matrix factorization (NMF or NNMF)****NMF with the Frobenius norm**

[NMF](#)<sup>1</sup> is an alternative approach to decomposition that assumes that the data and the components are non-negative. [NMF](#) can be plugged in instead of [PCA](#) or its variants, in the cases where the data matrix does not contain negative values. It finds a decomposition of samples  $X$  into two matrices  $W$  and  $H$  of non-negative elements, by optimizing the distance  $d$  between  $X$  and the matrix product  $WH$ . The most widely used distance function is the squared Frobenius

<sup>1</sup> “Learning the parts of objects by non-negative matrix factorization” D. Lee, S. Seung, 1999

norm, which is an obvious extension of the Euclidean norm to matrices:

$$d_{\text{Fro}}(X, Y) = \frac{1}{2} \|X - Y\|_{\text{Fro}}^2 = \frac{1}{2} \sum_{i,j} (X_{ij} - Y_{ij})^2$$

Unlike [PCA](#), the representation of a vector is obtained in an additive fashion, by superimposing the components, without subtracting. Such additive models are efficient for representing images and text.

It has been observed in [Hoyer, 2004]<sup>2</sup> that, when carefully constrained, [NMF](#) can produce a parts-based representation of the dataset, resulting in interpretable models. The following example displays 16 sparse components found by [NMF](#) from the images in the Olivetti faces dataset, in comparison with the PCA eigenfaces.

genfaces - PCA using randomized SVD - Train time 0.1

Non-negative components - NMF - Train time 0.4s

The `init` attribute determines the initialization method applied, which has a great impact on the performance of the method. [NMF](#) implements the method Nonnegative Double Singular Value Decomposition. NNDSVD<sup>4</sup> is based on two SVD processes, one approximating the data matrix, the other approximating positive sections of the resulting partial SVD factors utilizing an algebraic property of unit rank matrices. The basic NNDSVD algorithm is better fit for sparse factorization. Its variants NNDSVDA (in which all zeros are set equal to the mean of all elements of the data), and NNDSVDAR (in which the zeros are set to random perturbations less than the mean of the data divided by 100) are recommended in the dense case.

<sup>2</sup> “Non-negative Matrix Factorization with Sparseness Constraints” P. Hoyer, 2004

<sup>4</sup> “SVD based initialization: A head start for nonnegative matrix factorization” C. Boutsidis, E. Gallopolous, 2008

Note that the Multiplicative Update ('mu') solver cannot update zeros present in the initialization, so it leads to poorer results when used jointly with the basic NNDSVD algorithm which introduces a lot of zeros; in this case, NNDSVDA or NNDSVDar should be preferred.

`NMF` can also be initialized with correctly scaled random non-negative matrices by setting `init="random"`. An integer seed or a `RandomState` can also be passed to `random_state` to control reproducibility.

In `NMF`, L1 and L2 priors can be added to the loss function in order to regularize the model. The L2 prior uses the Frobenius norm, while the L1 prior uses an elementwise L1 norm. As in `ElasticNet`, we control the combination of L1 and L2 with the `l1_ratio` ( $\rho$ ) parameter, and the intensity of the regularization with the `alpha` ( $\alpha$ ) parameter. Then the priors terms are:

$$\alpha\rho\|W\|_1 + \alpha\rho\|H\|_1 + \frac{\alpha(1-\rho)}{2}\|W\|_{\text{Fro}}^2 + \frac{\alpha(1-\rho)}{2}\|H\|_{\text{Fro}}^2$$

and the regularized objective function is:

$$d_{\text{Fro}}(X, WH) + \alpha\rho\|W\|_1 + \alpha\rho\|H\|_1 + \frac{\alpha(1-\rho)}{2}\|W\|_{\text{Fro}}^2 + \frac{\alpha(1-\rho)}{2}\|H\|_{\text{Fro}}^2$$

`NMF` regularizes both W and H. The public function `non_negative_factorization` allows a finer control through the `regularization` attribute, and may regularize only W, only H, or both.

## NMF with a beta-divergence

As described previously, the most widely used distance function is the squared Frobenius norm, which is an obvious extension of the Euclidean norm to matrices:

$$d_{\text{Fro}}(X, Y) = \frac{1}{2}\|X - Y\|_{\text{Fro}}^2 = \frac{1}{2} \sum_{i,j} (X_{ij} - Y_{ij})^2$$

Other distance functions can be used in NMF as, for example, the (generalized) Kullback-Leibler (KL) divergence, also referred as I-divergence:

$$d_{KL}(X, Y) = \sum_{i,j} (X_{ij} \log(\frac{X_{ij}}{Y_{ij}}) - X_{ij} + Y_{ij})$$

Or, the Itakura-Saito (IS) divergence:

$$d_{IS}(X, Y) = \sum_{i,j} (\frac{X_{ij}}{Y_{ij}} - \log(\frac{X_{ij}}{Y_{ij}}) - 1)$$

These three distances are special cases of the beta-divergence family, with  $\beta = 2, 1, 0$  respectively<sup>6</sup>. The beta-divergence are defined by :

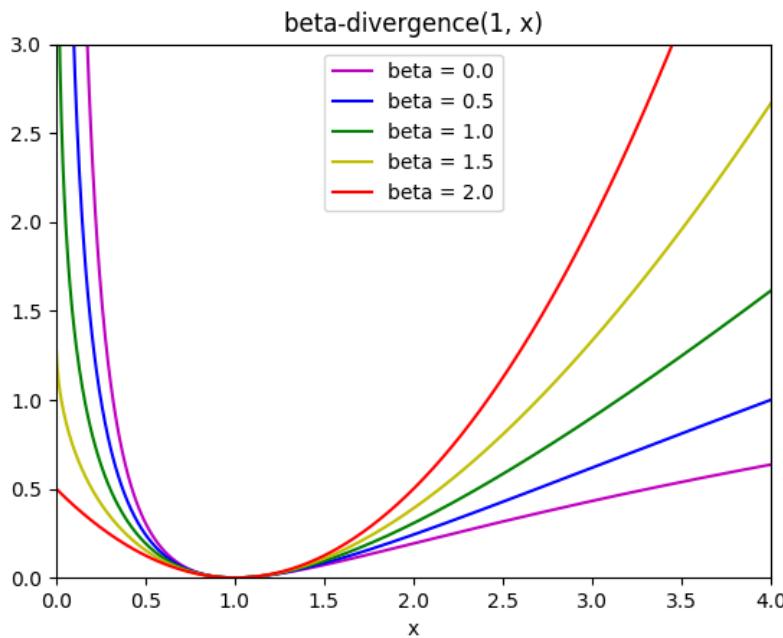

$$d_\beta(X, Y) = \sum_{i,j} \frac{1}{\beta(\beta-1)} (X_{ij}^\beta + (\beta-1)Y_{ij}^\beta - \beta X_{ij} Y_{ij}^{\beta-1})$$

Note that this definition is not valid if  $\beta \in (0; 1)$ , yet it can be continuously extended to the definitions of  $d_{KL}$  and  $d_{IS}$  respectively.

`NMF` implements two solvers, using Coordinate Descent ('cd')<sup>5</sup>, and Multiplicative Update ('mu')<sup>6</sup>. The 'mu' solver can optimize every beta-divergence, including of course the Frobenius norm ( $\beta = 2$ ), the (generalized) Kullback-Leibler divergence ( $\beta = 1$ ) and the Itakura-Saito divergence ( $\beta = 0$ ). Note that for  $\beta \in (1; 2)$ , the 'mu' solver is

<sup>6</sup> "Algorithms for nonnegative matrix factorization with the beta-divergence" C. Févotte, J. Idier, 2011

<sup>5</sup> "Fast local algorithms for large scale nonnegative matrix and tensor factorizations." A. Cichocki, P. Anh-Huy, 2009

significantly faster than for other values of  $\beta$ . Note also that with a negative (or 0, i.e. ‘itakura-saito’)  $\beta$ , the input matrix cannot contain zero values.

The ‘cd’ solver can only optimize the Frobenius norm. Due to the underlying non-convexity of NMF, the different solvers may converge to different minima, even when optimizing the same distance function.

NMF is best used with the `fit_transform` method, which returns the matrix W. The matrix H is stored into the fitted model in the `components_` attribute; the method `transform` will decompose a new matrix X\_new based on these stored components:

```
>>> import numpy as np
>>> X = np.array([[1, 1], [2, 1], [3, 1.2], [4, 1], [5, 0.8], [6, 1]])
>>> from sklearn.decomposition import NMF
>>> model = NMF(n_components=2, init='random', random_state=0)
>>> W = model.fit_transform(X)
>>> H = model.components_
>>> X_new = np.array([[1, 0], [1, 6.1], [1, 0], [1, 4], [3.2, 1], [0, 4]])
>>> W_new = model.transform(X_new)
```

## Latent Dirichlet Allocation (LDA)

Latent Dirichlet Allocation is a generative probabilistic model for collections of discrete dataset such as text corpora. It is also a topic model that is used for discovering abstract topics from a collection of documents.

The graphical model of LDA is a three-level Bayesian model:

When modeling text corpora, the model assumes the following generative process for a corpus with  $D$  documents and  $K$  topics:

1. For each topic  $k$ , draw  $\beta_k \sim \text{Dirichlet}(\eta)$ ,  $k = 1 \dots K$
2. For each document  $d$ , draw  $\theta_d \sim \text{Dirichlet}(\alpha)$ ,  $d = 1 \dots D$
3. For each word  $i$  in document  $d$ :
  1. Draw a topic index  $z_{di} \sim \text{Multinomial}(\theta_d)$
  2. Draw the observed word  $w_{ij} \sim \text{Multinomial}(\beta_{z_{di}})$

For parameter estimation, the posterior distribution is:

$$p(z, \theta, \beta | w, \alpha, \eta) = \frac{p(z, \theta, \beta | \alpha, \eta)}{p(w | \alpha, \eta)}$$

Since the posterior is intractable, variational Bayesian method uses a simpler distribution  $q(z, \theta, \beta | \lambda, \phi, \gamma)$  to approximate it, and those variational parameters  $\lambda, \phi, \gamma$  are optimized to maximize the Evidence Lower Bound (ELBO):

$$\log P(w | \alpha, \eta) \geq L(w, \phi, \gamma, \lambda) \triangleq E_q[\log p(w, z, \theta, \beta | \alpha, \eta)] - E_q[\log q(z, \theta, \beta)]$$

Maximizing ELBO is equivalent to minimizing the Kullback-Leibler(KL) divergence between  $q(z, \theta, \beta)$  and the true posterior  $p(z, \theta, \beta | w, \alpha, \eta)$ .

[LatentDirichletAllocation](#) implements online variational Bayes algorithm and supports both online and batch update method. While batch method updates variational variables after each full pass through the data, online method updates variational variables from mini-batch data points.

---

**Note:** Although online method is guaranteed to converge to a local optimum point, the quality of the optimum point and the speed of convergence may depend on mini-batch size and attributes related to learning rate setting.

---

When `LatentDirichletAllocation` is applied on a “document-term” matrix, the matrix will be decomposed into a “topic-term” matrix and a “document-topic” matrix. While “topic-term” matrix is stored as `components_` in the model, “document-topic” matrix can be calculated from `transform` method.

`LatentDirichletAllocation` also implements `partial_fit` method. This is used when data can be fetched sequentially.

### 3.2.6 Covariance estimation

Many statistical problems require at some point the estimation of a population’s covariance matrix, which can be seen as an estimation of data set scatter plot shape. Most of the time, such an estimation has to be done on a sample whose properties (size, structure, homogeneity) has a large influence on the estimation’s quality. The `sklearn.covariance` package aims at providing tools affording an accurate estimation of a population’s covariance matrix under various settings.

We assume that the observations are independent and identically distributed (i.i.d.).

#### Empirical covariance

The covariance matrix of a data set is known to be well approximated with the classical *maximum likelihood estimator* (or “empirical covariance”), provided the number of observations is large enough compared to the number of features (the variables describing the observations). More precisely, the Maximum Likelihood Estimator of a sample is an unbiased estimator of the corresponding population covariance matrix.

The empirical covariance matrix of a sample can be computed using the `empirical_covariance` function of the package, or by fitting an `EmpiricalCovariance` object to the data sample with the `EmpiricalCovariance.fit` method. Be careful that depending whether the data are centered or not, the result will be different, so one may want to use the `assume_centered` parameter accurately. More precisely if one uses `assume_centered=False`, then the test set is supposed to have the same mean vector as the training set. If not so, both should be centered by the user, and `assume_centered=True` should be used.

#### Examples:

- See *Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood* for an example on how to fit an `EmpiricalCovariance` object to data.

## Shrunk Covariance

### Basic shrinkage

Despite being an unbiased estimator of the covariance matrix, the Maximum Likelihood Estimator is not a good estimator of the eigenvalues of the covariance matrix, so the precision matrix obtained from its inversion is not accurate. Sometimes, it even occurs that the empirical covariance matrix cannot be inverted for numerical reasons. To avoid such an inversion problem, a transformation of the empirical covariance matrix has been introduced: the shrinkage.

In the scikit-learn, this transformation (with a user-defined shrinkage coefficient) can be directly applied to a pre-computed covariance with the `shrunk_covariance` method. Also, a shrunk estimator of the covariance can be fitted to data with a `ShrunkCovariance` object and its `ShrunkCovariance.fit` method. Again, depending whether the data are centered or not, the result will be different, so one may want to use the `assume_centered` parameter accurately.

Mathematically, this shrinkage consists in reducing the ratio between the smallest and the largest eigenvalue of the empirical covariance matrix. It can be done by simply shifting every eigenvalue according to a given offset, which is equivalent of finding the l2-penalized Maximum Likelihood Estimator of the covariance matrix. In practice, shrinkage boils down to a simple a convex transformation :  $\Sigma_{\text{shrunk}} = (1 - \alpha)\hat{\Sigma} + \alpha \frac{\text{Tr}\hat{\Sigma}}{p} \text{Id}$ .

Choosing the amount of shrinkage,  $\alpha$  amounts to setting a bias/variance trade-off, and is discussed below.

#### Examples:

- See [Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood](#) for an example on how to fit a `ShrunkCovariance` object to data.

## Ledoit-Wolf shrinkage

In their 2004 paper [1], O. Ledoit and M. Wolf propose a formula so as to compute the optimal shrinkage coefficient  $\alpha$  that minimizes the Mean Squared Error between the estimated and the real covariance matrix.

The Ledoit-Wolf estimator of the covariance matrix can be computed on a sample with the `ledoit_wolf` function of the `sklearn.covariance` package, or it can be otherwise obtained by fitting a `LedoitWolf` object to the same sample.

#### Examples:

- See [Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood](#) for an example on how to fit a `LedoitWolf` object to data and for visualizing the performances of the Ledoit-Wolf estimator in terms of likelihood.

[1] O. Ledoit and M. Wolf, “A Well-Conditioned Estimator for Large-Dimensional Covariance Matrices”, Journal of Multivariate Analysis, Volume 88, Issue 2, February 2004, pages 365-411.

## Oracle Approximating Shrinkage

Under the assumption that the data are Gaussian distributed, Chen et al. [2] derived a formula aimed at choosing a shrinkage coefficient that yields a smaller Mean Squared Error than the one given by Ledoit and Wolf’s formula. The resulting estimator is known as the Oracle Shrinkage Approximating estimator of the covariance.

The OAS estimator of the covariance matrix can be computed on a sample with the `oas` function of the `sklearn.covariance` package, or it can be otherwise obtained by fitting an `OAS` object to the same sample.

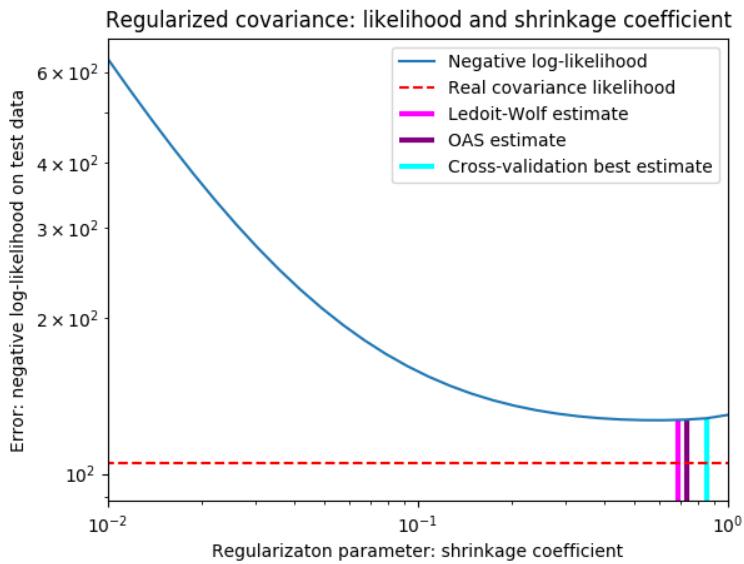

Fig. 3.7: Bias-variance trade-off when setting the shrinkage: comparing the choices of Ledoit-Wolf and OAS estimators

[2] Chen et al., “Shrinkage Algorithms for MMSE Covariance Estimation”, IEEE Trans. on Sign. Proc., Volume 58, Issue 10, October 2010.

#### Examples:

- See [Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood](#) for an example on how to fit an `OAS` object to data.
- See [Ledoit-Wolf vs OAS estimation](#) to visualize the Mean Squared Error difference between a `LedoitWolf` and an `OAS` estimator of the covariance.

#### Sparse inverse covariance

The matrix inverse of the covariance matrix, often called the precision matrix, is proportional to the partial correlation matrix. It gives the partial independence relationship. In other words, if two features are independent conditionally on the others, the corresponding coefficient in the precision matrix will be zero. This is why it makes sense to estimate a sparse precision matrix: by learning independence relations from the data, the estimation of the covariance matrix is better conditioned. This is known as *covariance selection*.

In the small-samples situation, in which `n_samples` is on the order of `n_features` or smaller, sparse inverse covariance estimators tend to work better than shrunk covariance estimators. However, in the opposite situation, or for very correlated data, they can be numerically unstable. In addition, unlike shrinkage estimators, sparse estimators are able to recover off-diagonal structure.

The `GraphLasso` estimator uses an  $\ell_1$  penalty to enforce sparsity on the precision matrix: the higher its `alpha` parameter, the more sparse the precision matrix. The corresponding `GraphLassoCV` object uses cross-validation to automatically set the `alpha` parameter.

---

#### Note: Structure recovery

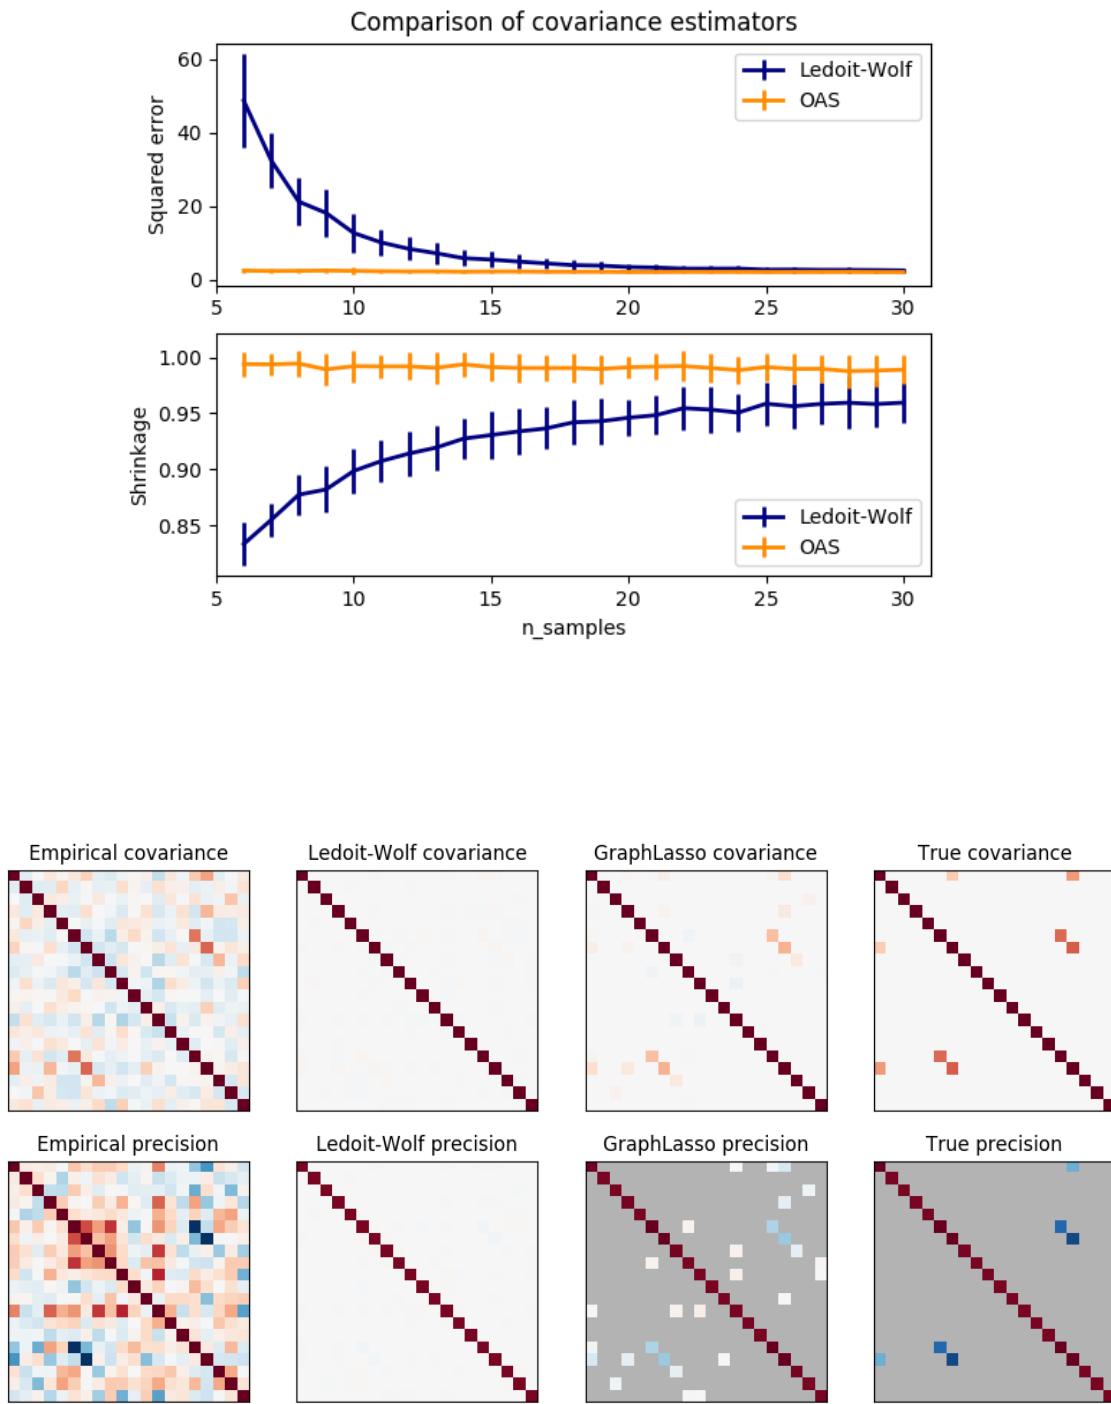

Fig. 3.8: A comparison of maximum likelihood, shrinkage and sparse estimates of the covariance and precision matrix in the very small samples settings.

Recovering a graphical structure from correlations in the data is a challenging thing. If you are interested in such recovery keep in mind that:

- Recovery is easier from a correlation matrix than a covariance matrix: standardize your observations before running `GraphLasso`
- If the underlying graph has nodes with much more connections than the average node, the algorithm will miss some of these connections.
- If your number of observations is not large compared to the number of edges in your underlying graph, you will not recover it.
- Even if you are in favorable recovery conditions, the alpha parameter chosen by cross-validation (e.g. using the `GraphLassoCV` object) will lead to selecting too many edges. However, the relevant edges will have heavier weights than the irrelevant ones.

The mathematical formulation is the following:

$$\hat{K} = \operatorname{argmin}_K (\operatorname{tr} SK - \log \det K + \alpha \|K\|_1)$$

Where  $K$  is the precision matrix to be estimated, and  $S$  is the sample covariance matrix.  $\|K\|_1$  is the sum of the absolute values of off-diagonal coefficients of  $K$ . The algorithm employed to solve this problem is the GLasso algorithm, from the Friedman 2008 Biostatistics paper. It is the same algorithm as in the R `glasso` package.

#### Examples:

- *Sparse inverse covariance estimation*: example on synthetic data showing some recovery of a structure, and comparing to other covariance estimators.
- *Visualizing the stock market structure*: example on real stock market data, finding which symbols are most linked.

## Robust Covariance Estimation

Real data set are often subjects to measurement or recording errors. Regular but uncommon observations may also appear for a variety of reason. Every observation which is very uncommon is called an outlier. The empirical covariance estimator and the shrunk covariance estimators presented above are very sensitive to the presence of outlying observations in the data. Therefore, one should use robust covariance estimators to estimate the covariance of its real data sets. Alternatively, robust covariance estimators can be used to perform outlier detection and discard/downweight some observations according to further processing of the data.

The `sklearn.covariance` package implements a robust estimator of covariance, the Minimum Covariance Determinant [3].

## Minimum Covariance Determinant

The Minimum Covariance Determinant estimator is a robust estimator of a data set’s covariance introduced by P.J. Rousseeuw in [3]. The idea is to find a given proportion ( $h$ ) of “good” observations which are not outliers and compute

their empirical covariance matrix. This empirical covariance matrix is then rescaled to compensate the performed selection of observations (“consistency step”). Having computed the Minimum Covariance Determinant estimator, one can give weights to observations according to their Mahalanobis distance, leading to a reweighted estimate of the covariance matrix of the data set (“reweighting step”).

Rousseeuw and Van Driessen [4] developed the FastMCD algorithm in order to compute the Minimum Covariance Determinant. This algorithm is used in scikit-learn when fitting an MCD object to data. The FastMCD algorithm also computes a robust estimate of the data set location at the same time.

Raw estimates can be accessed as `raw_location_` and `raw_covariance_` attributes of a `MinCovDet` robust covariance estimator object.

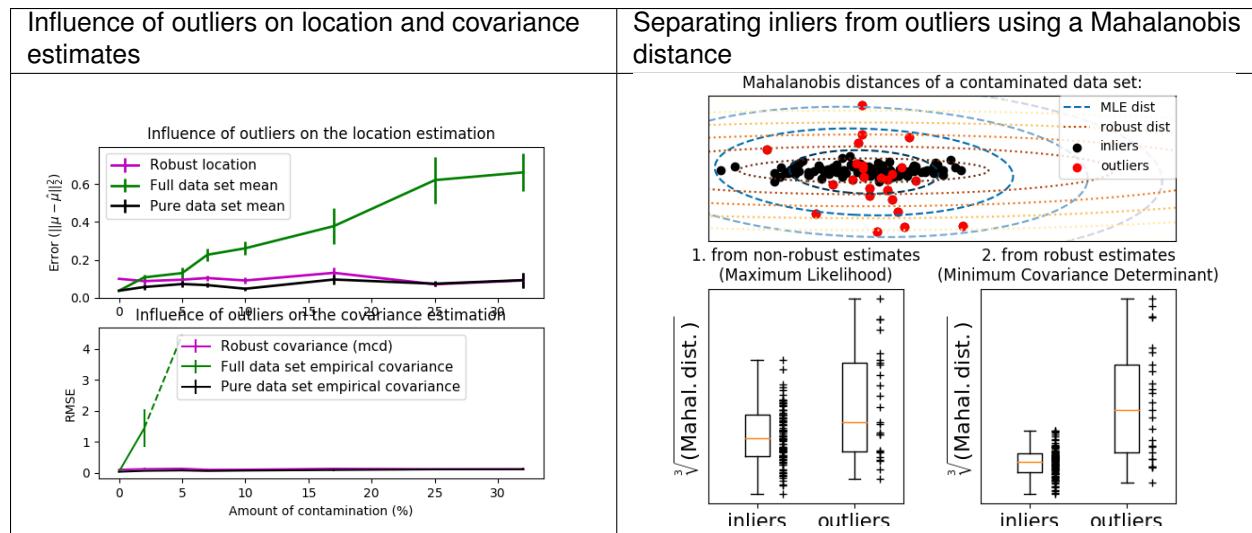

### [3] P. J. Rousseeuw. Least median of squares regression.

10. Am Stat Ass, 79:871, 1984.

### [4] A Fast Algorithm for the Minimum Covariance Determinant Estimator, 1999, American Statistical Association and the American Society for Quality, TECHNOMETRICS.

#### Examples:

- See [Robust vs Empirical covariance estimate](#) for an example on how to fit a `MinCovDet` object to data and see how the estimate remains accurate despite the presence of outliers.
- See [Robust covariance estimation and Mahalanobis distances relevance](#) to visualize the difference between `EmpiricalCovariance` and `MinCovDet` covariance estimators in terms of Mahalanobis distance (so we get a better estimate of the precision matrix too).

## 3.2.7 Novelty and Outlier Detection

Many applications require being able to decide whether a new observation belongs to the same distribution as existing observations (it is an *inlier*), or should be considered as different (it is an *outlier*). Often, this ability is used to clean real data sets. Two important distinction must be made:

**novelty detection** The training data is not polluted by outliers, and we are interested in detecting anomalies in new observations.

**outlier detection** The training data contains outliers, and we need to fit the central mode of the training data, ignoring the deviant observations.

The scikit-learn project provides a set of machine learning tools that can be used both for novelty or outliers detection. This strategy is implemented with objects learning in an unsupervised way from the data:

```
estimator.fit(X_train)
```

new observations can then be sorted as inliers or outliers with a *predict* method:

```
estimator.predict(X_test)
```

Inliers are labeled 1, while outliers are labeled -1.

## Novelty Detection

Consider a data set of  $n$  observations from the same distribution described by  $p$  features. Consider now that we add one more observation to that data set. Is the new observation so different from the others that we can doubt it is regular? (i.e. does it come from the same distribution?) Or on the contrary, is it so similar to the other that we cannot distinguish it from the original observations? This is the question addressed by the novelty detection tools and methods.

In general, it is about to learn a rough, close frontier delimiting the contour of the initial observations distribution, plotted in embedding  $p$ -dimensional space. Then, if further observations lay within the frontier-delimited subspace, they are considered as coming from the same population than the initial observations. Otherwise, if they lay outside the frontier, we can say that they are abnormal with a given confidence in our assessment.

The One-Class SVM has been introduced by Schölkopf et al. for that purpose and implemented in the *Support Vector Machines* module in the `svm.OneClassSVM` object. It requires the choice of a kernel and a scalar parameter to define a frontier. The RBF kernel is usually chosen although there exists no exact formula or algorithm to set its bandwidth parameter. This is the default in the scikit-learn implementation. The  $\nu$  parameter, also known as the margin of the One-Class SVM, corresponds to the probability of finding a new, but regular, observation outside the frontier.

### Examples:

- See *One-class SVM with non-linear kernel (RBF)* for visualizing the frontier learned around some data by a `svm.OneClassSVM` object.

## Outlier Detection

Outlier detection is similar to novelty detection in the sense that the goal is to separate a core of regular observations from some polluting ones, called “outliers”. Yet, in the case of outlier detection, we don’t have a clean data set representing the population of regular observations that can be used to train any tool.

### Fitting an elliptic envelope

One common way of performing outlier detection is to assume that the regular data come from a known distribution (e.g. data are Gaussian distributed). From this assumption, we generally try to define the “shape” of the data, and can define outlying observations as observations which stand far enough from the fit shape.

The scikit-learn provides an object `covariance.EllipticEnvelope` that fits a robust covariance estimate to the data, and thus fits an ellipse to the central data points, ignoring points outside the central mode.

For instance, assuming that the inlier data are Gaussian distributed, it will estimate the inlier location and covariance in a robust way (i.e. without being influenced by outliers). The Mahalanobis distances obtained from this estimate is used to derive a measure of outlyingness. This strategy is illustrated below.

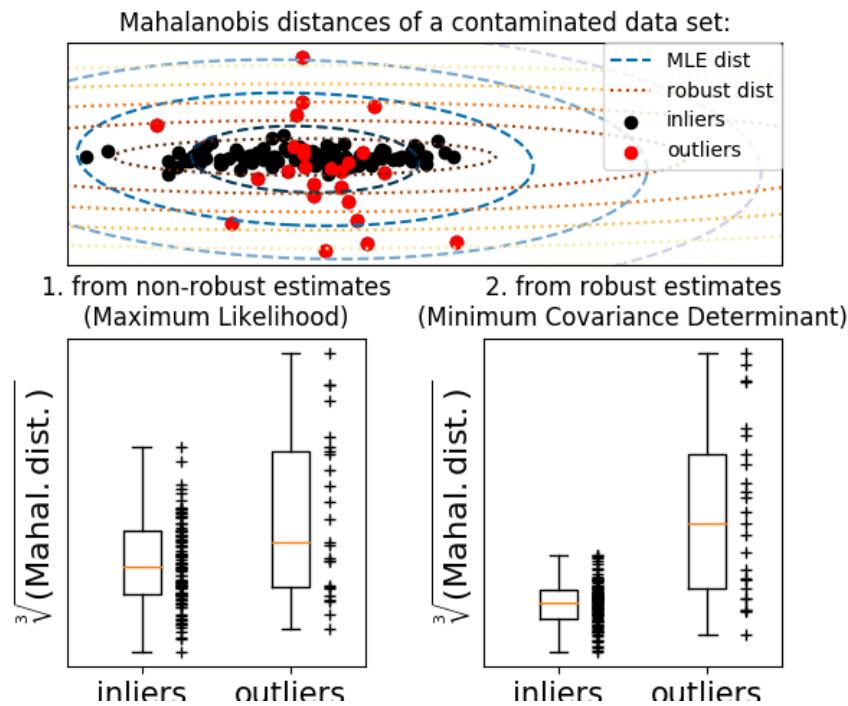

#### Examples:

- See [Robust covariance estimation and Mahalanobis distances relevance](#) for an illustration of the difference between using a standard (`covariance.EmpiricalCovariance`) or a robust estimate (`covariance.MinCovDet`) of location and covariance to assess the degree of outlyingness of an observation.

#### References:

### Isolation Forest

One efficient way of performing outlier detection in high-dimensional datasets is to use random forests. The `ensemble.IsolationForest` ‘isolates’ observations by randomly selecting a feature and then randomly selecting a split value between the maximum and minimum values of the selected feature.

Since recursive partitioning can be represented by a tree structure, the number of splittings required to isolate a sample is equivalent to the path length from the root node to the terminating node.

This path length, averaged over a forest of such random trees, is a measure of normality and our decision function.

Random partitioning produces noticeably shorter paths for anomalies. Hence, when a forest of random trees collectively produce shorter path lengths for particular samples, they are highly likely to be anomalies.

This strategy is illustrated below.

#### Examples:

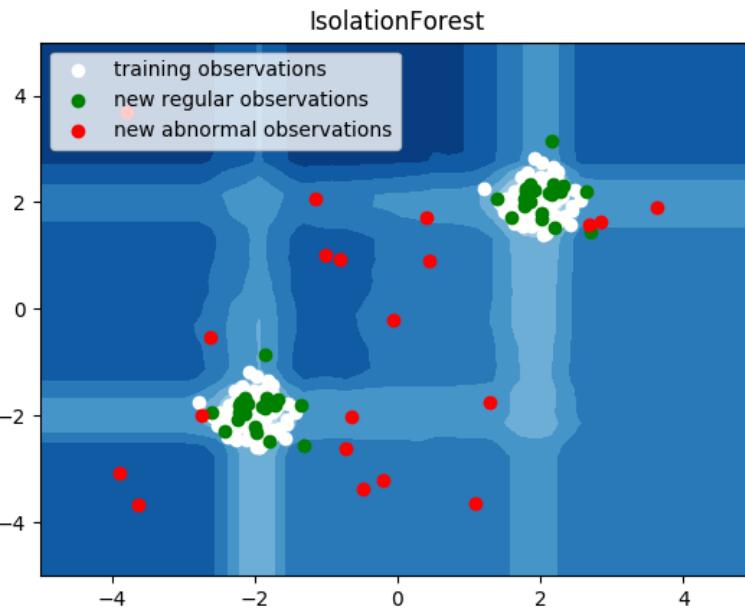

- See [IsolationForest example](#) for an illustration of the use of IsolationForest.
- See [Outlier detection with several methods](#). for a comparison of `ensemble.IsolationForest` with `neighbors.LocalOutlierFactor`, `svm.OneClassSVM` (tuned to perform like an outlier detection method) and a covariance-based outlier detection with `covariance.EllipticEnvelope`.

#### References:

### Local Outlier Factor

Another efficient way to perform outlier detection on moderately high dimensional datasets is to use the Local Outlier Factor (LOF) algorithm.

The `neighbors.LocalOutlierFactor` (LOF) algorithm computes a score (called local outlier factor) reflecting the degree of abnormality of the observations. It measures the local density deviation of a given data point with respect to its neighbors. The idea is to detect the samples that have a substantially lower density than their neighbors.

In practice the local density is obtained from the k-nearest neighbors. The LOF score of an observation is equal to the ratio of the average local density of his k-nearest neighbors, and its own local density: a normal instance is expected to have a local density similar to that of its neighbors, while abnormal data are expected to have much smaller local density.

The number k of neighbors considered, (alias parameter `n_neighbors`) is typically chosen 1) greater than the minimum number of objects a cluster has to contain, so that other objects can be local outliers relative to this cluster, and 2) smaller than the maximum number of close by objects that can potentially be local outliers. In practice, such informations are generally not available, and taking `n_neighbors=20` appears to work well in general. When the proportion of outliers is high (i.e. greater than 10 %, as in the example below), `n_neighbors` should be greater (`n_neighbors=35` in the example below).

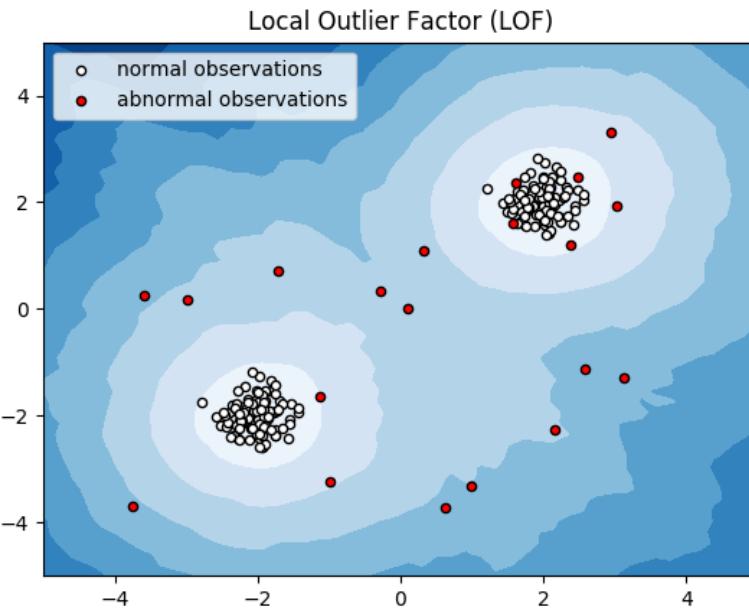

The strength of the LOF algorithm is that it takes both local and global properties of datasets into consideration: it can perform well even in datasets where abnormal samples have different underlying densities. The question is not, how isolated the sample is, but how isolated it is with respect to the surrounding neighborhood.

This strategy is illustrated below.

#### Examples:

- See `sphx_glr_auto_example_neighbors_plot_lof.py` for an illustration of the use of `neighbors.LocalOutlierFactor`.
- See `sphx_glr_auto_example_covariance_plot_outlier_detection.py` for a comparison with other anomaly detection methods.

#### References:

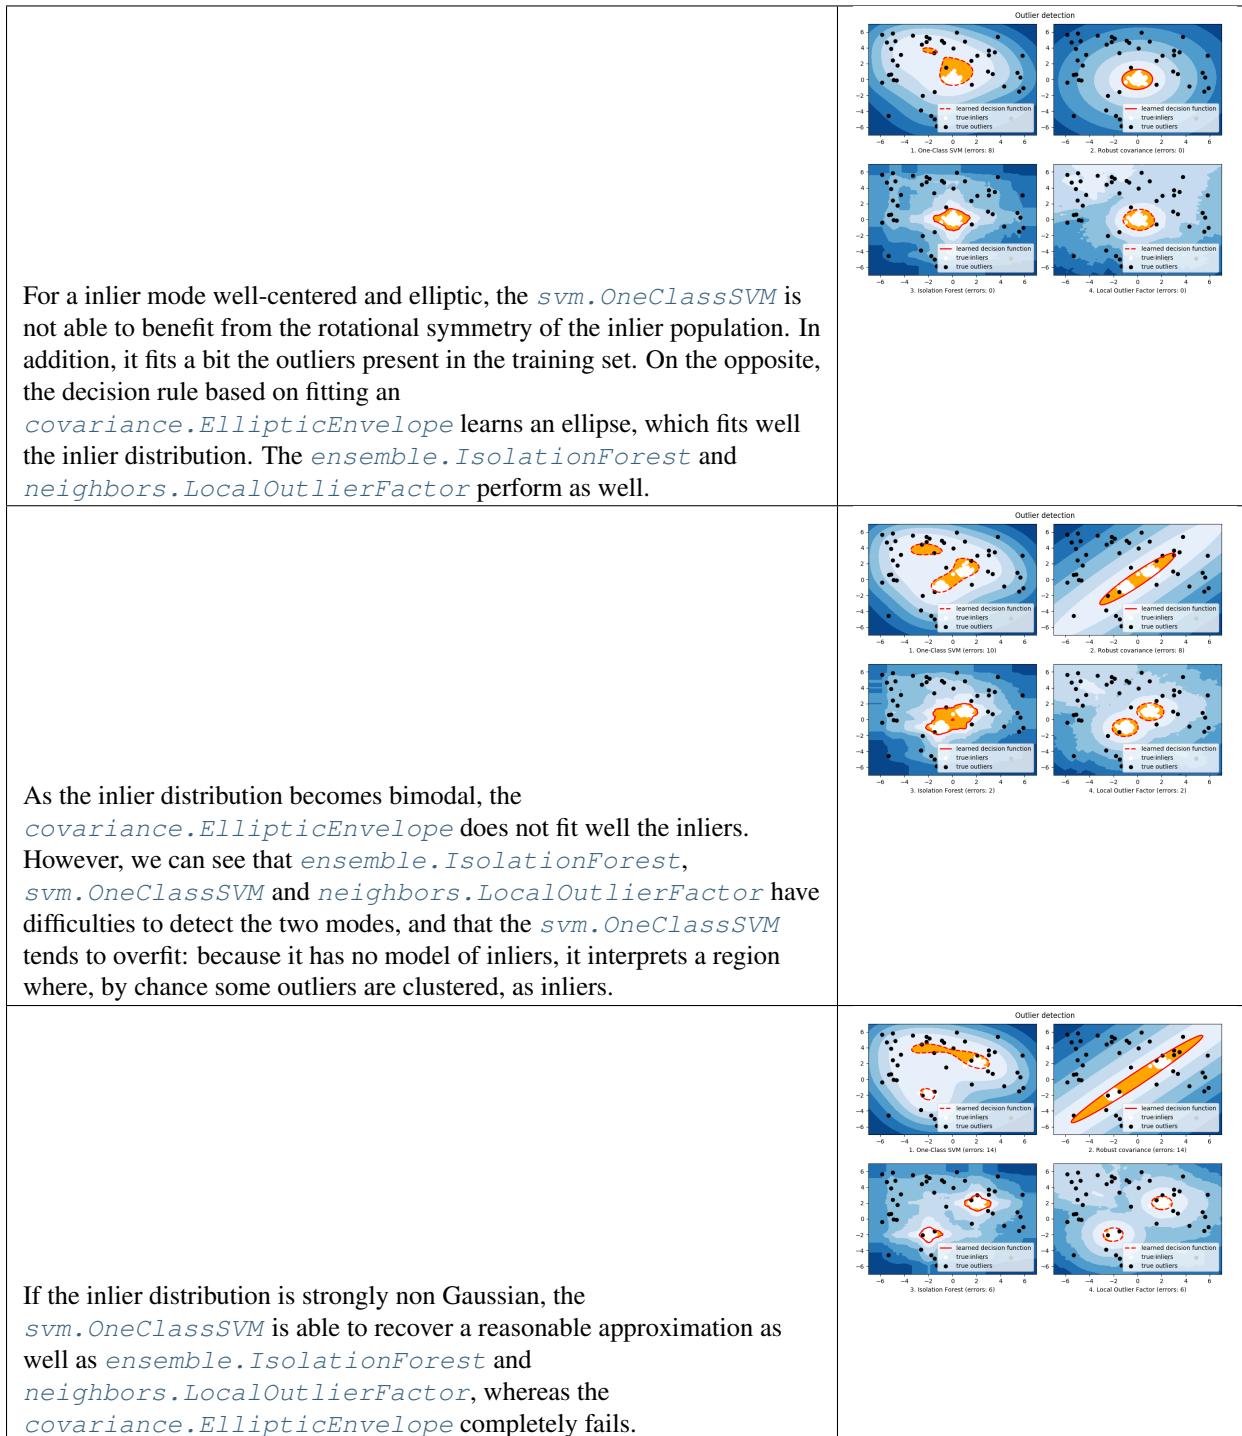

### One-class SVM versus Elliptic Envelope versus Isolation Forest versus LOF

Strictly-speaking, the One-class SVM is not an outlier-detection method, but a novelty-detection method: its training set should not be contaminated by outliers as it may fit them. That said, outlier detection in high-dimension, or without any assumptions on the distribution of the inlying data is very challenging, and a One-class SVM gives useful results in these situations.

The examples below illustrate how the performance of the `covariance.EllipticEnvelope` degrades as the data is less and less unimodal. The `svm.OneClassSVM` works better on data with multiple modes and `ensemble.IsolationForest` and `neighbors.LocalOutlierFactor` perform well in every cases.

Table 3.1: Comparing One-class SVM, Isolation Forest, LOF, and Elliptic Envelope

**Examples:**

- See [Outlier detection with several methods](#). for a comparison of the `svm.OneClassSVM` (tuned to perform like an outlier detection method), the `ensemble.IsolationForest`, the `neighbors.LocalOutlierFactor` and a covariance-based outlier detection `covariance.EllipticEnvelope`.

*EllipticEnvelope.*

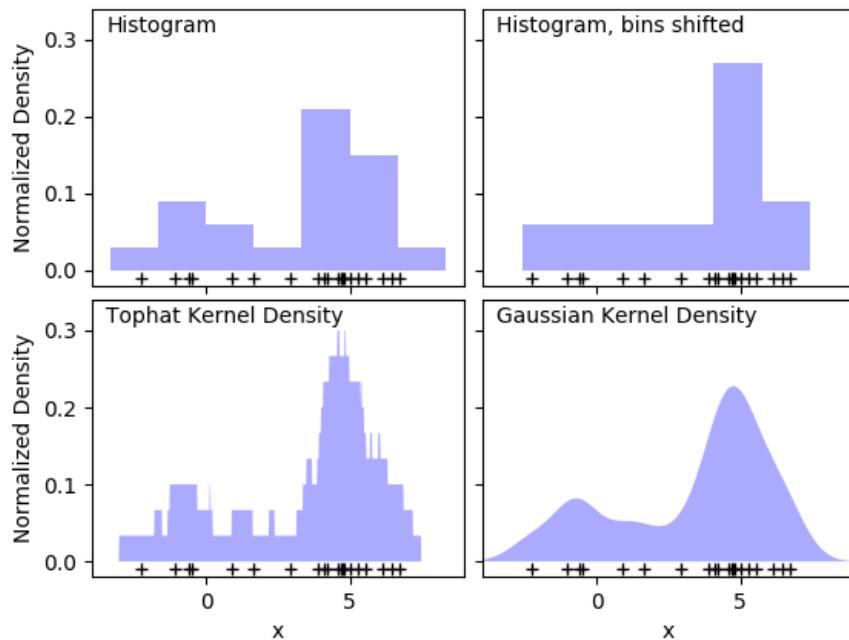

### 3.2.8 Density Estimation

Density estimation walks the line between unsupervised learning, feature engineering, and data modeling. Some of the most popular and useful density estimation techniques are mixture models such as Gaussian Mixtures ([sklearn.mixture.GaussianMixture](#)), and neighbor-based approaches such as the kernel density estimate ([sklearn.neighbors.KernelDensity](#)). Gaussian Mixtures are discussed more fully in the context of *clustering*, because the technique is also useful as an unsupervised clustering scheme.

Density estimation is a very simple concept, and most people are already familiar with one common density estimation technique: the histogram.

#### Density Estimation: Histograms

A histogram is a simple visualization of data where bins are defined, and the number of data points within each bin is tallied. An example of a histogram can be seen in the upper-left panel of the following figure:

A major problem with histograms, however, is that the choice of binning can have a disproportionate effect on the resulting visualization. Consider the upper-right panel of the above figure. It shows a histogram over the same data, with the bins shifted right. The results of the two visualizations look entirely different, and might lead to different interpretations of the data.

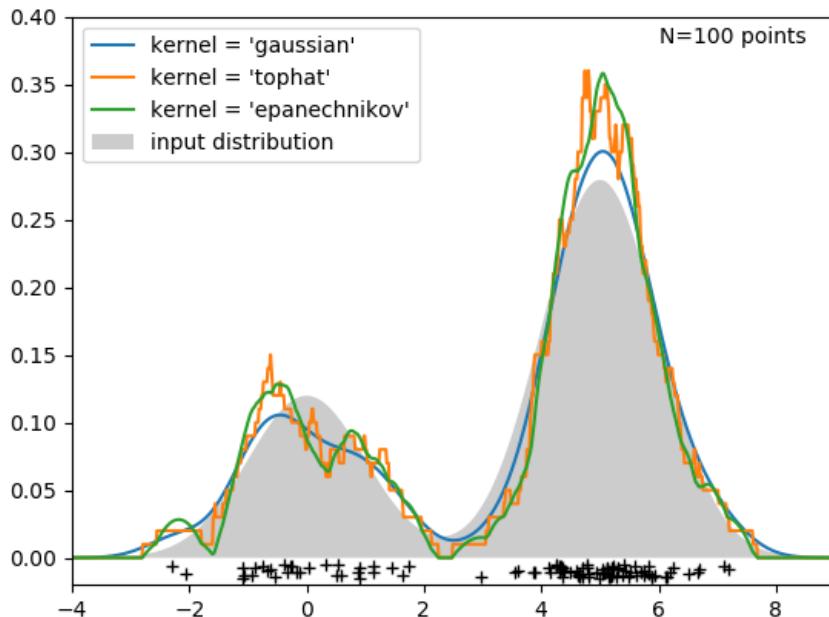

Intuitively, one can also think of a histogram as a stack of blocks, one block per point. By stacking the blocks in the appropriate grid space, we recover the histogram. But what if, instead of stacking the blocks on a regular grid, we center each block on the point it represents, and sum the total height at each location? This idea leads to the lower-left visualization. It is perhaps not as clean as a histogram, but the fact that the data drive the block locations mean that it is a much better representation of the underlying data.

This visualization is an example of a *kernel density estimation*, in this case with a top-hat kernel (i.e. a square block at each point). We can recover a smoother distribution by using a smoother kernel. The bottom-right plot shows a Gaussian kernel density estimate, in which each point contributes a Gaussian curve to the total. The result is a smooth density estimate which is derived from the data, and functions as a powerful non-parametric model of the distribution of points.

## Kernel Density Estimation

Kernel density estimation in scikit-learn is implemented in the `sklearn.neighbors.KernelDensity` estimator, which uses the Ball Tree or KD Tree for efficient queries (see [Nearest Neighbors](#) for a discussion of these). Though the above example uses a 1D data set for simplicity, kernel density estimation can be performed in any number of dimensions, though in practice the curse of dimensionality causes its performance to degrade in high dimensions.

In the following figure, 100 points are drawn from a bimodal distribution, and the kernel density estimates are shown for three choices of kernels:

It's clear how the kernel shape affects the smoothness of the resulting distribution. The scikit-learn kernel density estimator can be used as follows:

```
>>> from sklearn.neighbors.kde import KernelDensity
>>> import numpy as np
>>> X = np.array([[-1, -1], [-2, -1], [-3, -2], [1, 1], [2, 1], [3, 2]])
>>> kde = KernelDensity(kernel='gaussian', bandwidth=0.2).fit(X)
>>> kde.score_samples(X)
array([-0.41075698, -0.41075698, -0.41076071, -0.41075698, -0.41075698,
       -0.41076071])
```

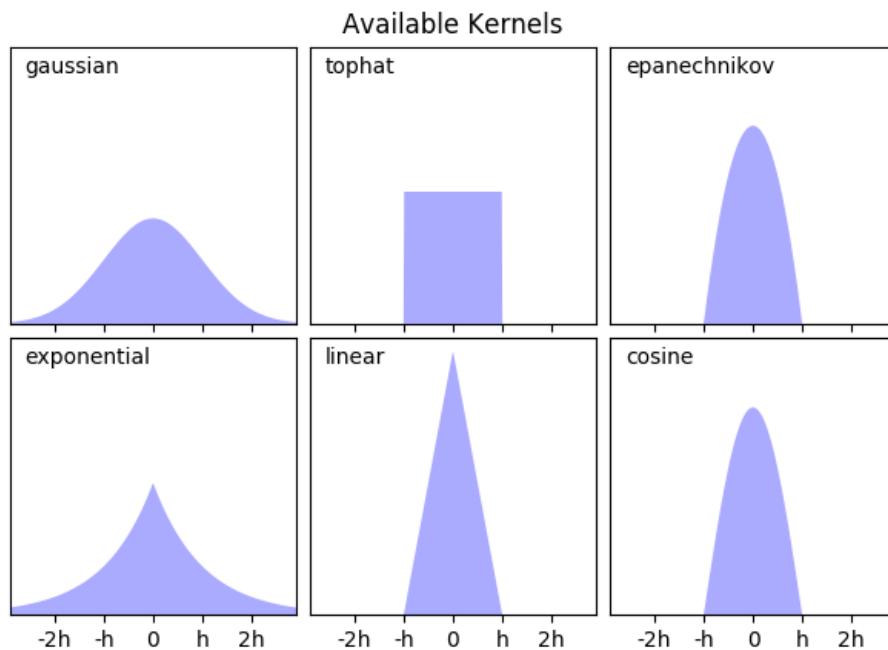

Here we have used `kernel='gaussian'`, as seen above. Mathematically, a kernel is a positive function  $K(x; h)$  which is controlled by the bandwidth parameter  $h$ . Given this kernel form, the density estimate at a point  $y$  within a

group of points  $x_i; i = 1 \dots N$  is given by:

$$\rho_K(y) = \sum_{i=1}^N K((y - x_i)/h)$$

The bandwidth here acts as a smoothing parameter, controlling the tradeoff between bias and variance in the result. A large bandwidth leads to a very smooth (i.e. high-bias) density distribution. A small bandwidth leads to an unsmooth (i.e. high-variance) density distribution.

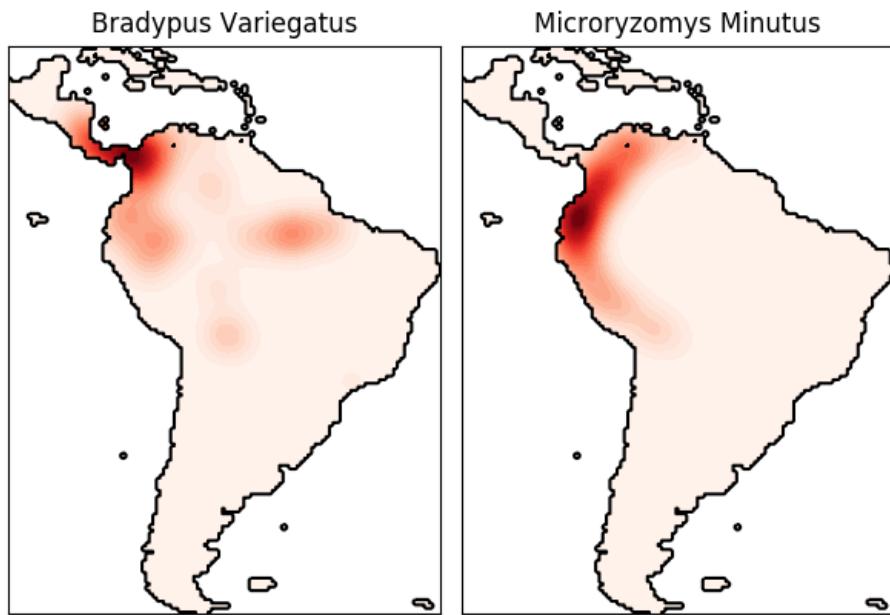

`sklearn.neighbors.KernelDensity` implements several common kernel forms, which are shown in the following figure:

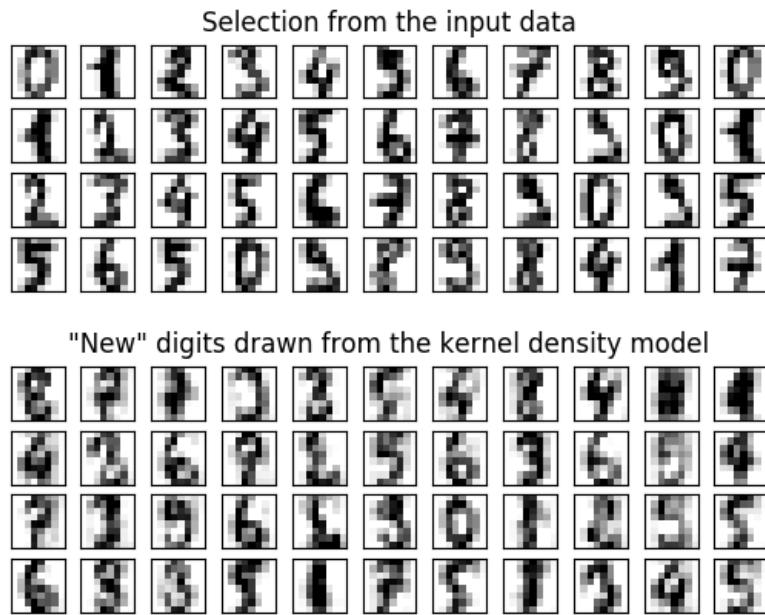

The form of these kernels is as follows:

- Gaussian kernel (`kernel = 'gaussian'`)  
 $K(x; h) \propto \exp(-\frac{x^2}{2h^2})$
- Tophat kernel (`kernel = 'tophat'`)  
 $K(x; h) \propto 1 \text{ if } x < h$
- Epanechnikov kernel (`kernel = 'epanechnikov'`)  
 $K(x; h) \propto 1 - \frac{x^2}{h^2}$
- Exponential kernel (`kernel = 'exponential'`)  
 $K(x; h) \propto \exp(-x/h)$
- Linear kernel (`kernel = 'linear'`)  
 $K(x; h) \propto 1 - x/h \text{ if } x < h$
- Cosine kernel (`kernel = 'cosine'`)  
 $K(x; h) \propto \cos(\frac{\pi x}{2h}) \text{ if } x < h$

The kernel density estimator can be used with any of the valid distance metrics (see `sklearn.neighbors.DistanceMetric` for a list of available metrics), though the results are properly normalized only for the Euclidean metric. One particularly useful metric is the `Haversine` distance which measures the angular distance between points on a sphere. Here is an example of using a kernel density estimate for a visualization of geospatial data, in this case the distribution of observations of two different species on the South American continent:

One other useful application of kernel density estimation is to learn a non-parametric generative model of a dataset in order to efficiently draw new samples from this generative model. Here is an example of using this process to create a new set of hand-written digits, using a Gaussian kernel learned on a PCA projection of the data:

The “new” data consists of linear combinations of the input data, with weights probabilistically drawn given the KDE model.

#### Examples:

- *Simple 1D Kernel Density Estimation*: computation of simple kernel density estimates in one dimension.
- *Kernel Density Estimation*: an example of using Kernel Density estimation to learn a generative model of the hand-written digits data, and drawing new samples from this model.
- *Kernel Density Estimate of Species Distributions*: an example of Kernel Density estimation using the Haversine distance metric to visualize geospatial data

### 3.2.9 Neural network models (unsupervised)

#### Restricted Boltzmann machines

Restricted Boltzmann machines (RBM) are unsupervised nonlinear feature learners based on a probabilistic model. The features extracted by an RBM or a hierarchy of RBMs often give good results when fed into a linear classifier such as a linear SVM or a perceptron.

The model makes assumptions regarding the distribution of inputs. At the moment, scikit-learn only provides [BernoulliRBM](#), which assumes the inputs are either binary values or values between 0 and 1, each encoding the probability that the specific feature would be turned on.

The RBM tries to maximize the likelihood of the data using a particular graphical model. The parameter learning algorithm used ([Stochastic Maximum Likelihood](#)) prevents the representations from straying far from the input data, which makes them capture interesting regularities, but makes the model less useful for small datasets, and usually not useful for density estimation.

The method gained popularity for initializing deep neural networks with the weights of independent RBMs. This method is known as unsupervised pre-training.

## 100 components extracted by RBM

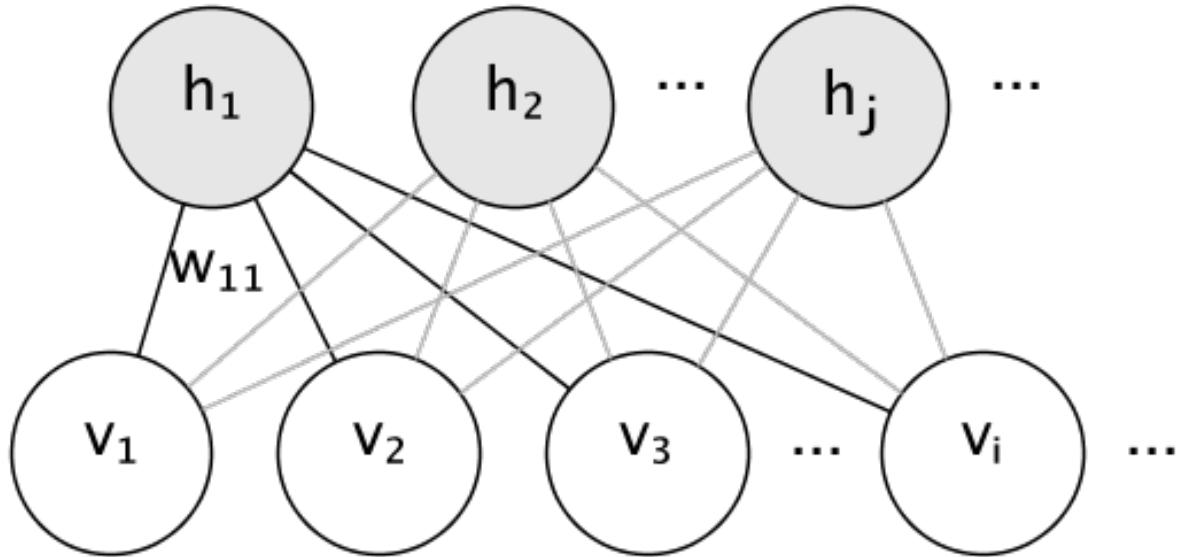

### Examples:

- *Restricted Boltzmann Machine features for digit classification*

### Graphical model and parametrization

The graphical model of an RBM is a fully-connected bipartite graph.

The nodes are random variables whose states depend on the state of the other nodes they are connected to. The model is therefore parameterized by the weights of the connections, as well as one intercept (bias) term for each visible and hidden unit, omitted from the image for simplicity.

The energy function measures the quality of a joint assignment:

$$E(\mathbf{v}, \mathbf{h}) = \sum_i \sum_j w_{ij} v_i h_j + \sum_i b_i v_i + \sum_j c_j h_j$$

In the formula above,  $\mathbf{b}$  and  $\mathbf{c}$  are the intercept vectors for the visible and hidden layers, respectively. The joint probability of the model is defined in terms of the energy:

$$P(\mathbf{v}, \mathbf{h}) = \frac{e^{-E(\mathbf{v}, \mathbf{h})}}{Z}$$

The word *restricted* refers to the bipartite structure of the model, which prohibits direct interaction between hidden units, or between visible units. This means that the following conditional independencies are assumed:

$$\begin{aligned} h_i &\perp h_j \mid \mathbf{v} \\ v_i &\perp v_j \mid \mathbf{h} \end{aligned}$$

The bipartite structure allows for the use of efficient block Gibbs sampling for inference.

### Bernoulli Restricted Boltzmann machines

In the *Bernoulli RBM*, all units are binary stochastic units. This means that the input data should either be binary, or real-valued between 0 and 1 signifying the probability that the visible unit would turn on or off. This is a good model for character recognition, where the interest is on which pixels are active and which aren't. For images of natural scenes it no longer fits because of background, depth and the tendency of neighbouring pixels to take the same values.

The conditional probability distribution of each unit is given by the logistic sigmoid activation function of the input it receives:

$$\begin{aligned} P(v_i = 1 \mid \mathbf{h}) &= \sigma\left(\sum_j w_{ij} h_j + b_i\right) \\ P(h_i = 1 \mid \mathbf{v}) &= \sigma\left(\sum_i w_{ij} v_i + c_j\right) \end{aligned}$$

where  $\sigma$  is the logistic sigmoid function:

$$\sigma(x) = \frac{1}{1 + e^{-x}}$$

## Stochastic Maximum Likelihood learning

The training algorithm implemented in `BernoulliRBM` is known as Stochastic Maximum Likelihood (SML) or Persistent Contrastive Divergence (PCD). Optimizing maximum likelihood directly is infeasible because of the form of the data likelihood:

$$\log P(v) = \log \sum_h e^{-E(v,h)} - \log \sum_{x,y} e^{-E(x,y)}$$

For simplicity the equation above is written for a single training example. The gradient with respect to the weights is formed of two terms corresponding to the ones above. They are usually known as the positive gradient and the negative gradient, because of their respective signs. In this implementation, the gradients are estimated over mini-batches of samples.

In maximizing the log-likelihood, the positive gradient makes the model prefer hidden states that are compatible with the observed training data. Because of the bipartite structure of RBMs, it can be computed efficiently. The negative gradient, however, is intractable. Its goal is to lower the energy of joint states that the model prefers, therefore making it stay true to the data. It can be approximated by Markov chain Monte Carlo using block Gibbs sampling by iteratively sampling each of  $v$  and  $h$  given the other, until the chain mixes. Samples generated in this way are sometimes referred as fantasy particles. This is inefficient and it is difficult to determine whether the Markov chain mixes.

The Contrastive Divergence method suggests to stop the chain after a small number of iterations,  $k$ , usually even 1. This method is fast and has low variance, but the samples are far from the model distribution.

Persistent Contrastive Divergence addresses this. Instead of starting a new chain each time the gradient is needed, and performing only one Gibbs sampling step, in PCD we keep a number of chains (fantasy particles) that are updated  $k$  Gibbs steps after each weight update. This allows the particles to explore the space more thoroughly.

## 3.3 Model selection and evaluation

### 3.3.1 Cross-validation: evaluating estimator performance

Learning the parameters of a prediction function and testing it on the same data is a methodological mistake: a model that would just repeat the labels of the samples that it has just seen would have a perfect score but would fail to predict anything useful on yet-unseen data. This situation is called **overfitting**. To avoid it, it is common practice when performing a (supervised) machine learning experiment to hold out part of the available data as a **test set** `X_test`, `y_test`. Note that the word “experiment” is not intended to denote academic use only, because even in commercial settings machine learning usually starts out experimentally.

In scikit-learn a random split into training and test sets can be quickly computed with the `train_test_split` helper function. Let’s load the iris data set to fit a linear support vector machine on it:

```
>>> import numpy as np
>>> from sklearn.model_selection import train_test_split
>>> from sklearn import datasets
>>> from sklearn import svm

>>> iris = datasets.load_iris()
>>> iris.data.shape, iris.target.shape
((150, 4), (150,))
```

We can now quickly sample a training set while holding out 40% of the data for testing (evaluating) our classifier:

```
>>> X_train, X_test, y_train, y_test = train_test_split(
...     iris.data, iris.target, test_size=0.4, random_state=0)

>>> X_train.shape, y_train.shape
((90, 4), (90,))
>>> X_test.shape, y_test.shape
((60, 4), (60,))

>>> clf = svm.SVC(kernel='linear', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.96...
```

When evaluating different settings (“hyperparameters”) for estimators, such as the  $C$  setting that must be manually set for an SVM, there is still a risk of overfitting *on the test set* because the parameters can be tweaked until the estimator performs optimally. This way, knowledge about the test set can “leak” into the model and evaluation metrics no longer report on generalization performance. To solve this problem, yet another part of the dataset can be held out as a so-called “validation set”: training proceeds on the training set, after which evaluation is done on the validation set, and when the experiment seems to be successful, final evaluation can be done on the test set.

However, by partitioning the available data into three sets, we drastically reduce the number of samples which can be used for learning the model, and the results can depend on a particular random choice for the pair of (train, validation) sets.

A solution to this problem is a procedure called [cross-validation](#) (CV for short). A test set should still be held out for final evaluation, but the validation set is no longer needed when doing CV. In the basic approach, called  $k$ -fold CV, the training set is split into  $k$  smaller sets (other approaches are described below, but generally follow the same principles). The following procedure is followed for each of the  $k$  “folds”:

- A model is trained using  $k - 1$  of the folds as training data;
- the resulting model is validated on the remaining part of the data (i.e., it is used as a test set to compute a performance measure such as accuracy).

The performance measure reported by  $k$ -fold cross-validation is then the average of the values computed in the loop. This approach can be computationally expensive, but does not waste too much data (as it is the case when fixing an arbitrary test set), which is a major advantage in problem such as inverse inference where the number of samples is very small.

## Computing cross-validated metrics

The simplest way to use cross-validation is to call the `cross_val_score` helper function on the estimator and the dataset.

The following example demonstrates how to estimate the accuracy of a linear kernel support vector machine on the iris dataset by splitting the data, fitting a model and computing the score 5 consecutive times (with different splits each time):

```
>>> from sklearn.model_selection import cross_val_score
>>> clf = svm.SVC(kernel='linear', C=1)
>>> scores = cross_val_score(clf, iris.data, iris.target, cv=5)
>>> scores
array([ 0.96...,  1.  ...,  0.96...,  0.96...,  1.        ])
```

The mean score and the 95% confidence interval of the score estimate are hence given by:

```
>>> print("Accuracy: %0.2f (+/- %0.2f)" % (scores.mean(), scores.std() * 2))
Accuracy: 0.98 (+/- 0.03)
```

By default, the score computed at each CV iteration is the `score` method of the estimator. It is possible to change this by using the `scoring` parameter:

```
>>> from sklearn import metrics
>>> scores = cross_val_score(
...     clf, iris.data, iris.target, cv=5, scoring='f1_macro')
>>> scores
array([ 0.96...,  1.  ...,  0.96...,  0.96...,  1.        ])
```

See [The scoring parameter: defining model evaluation rules](#) for details. In the case of the Iris dataset, the samples are balanced across target classes hence the accuracy and the F1-score are almost equal.

When the `cv` argument is an integer, `cross_val_score` uses the `KFold` or `StratifiedKFold` strategies by default, the latter being used if the estimator derives from `ClassifierMixin`.

It is also possible to use other cross validation strategies by passing a cross validation iterator instead, for instance:

```
>>> from sklearn.model_selection import ShuffleSplit
>>> n_samples = iris.data.shape[0]
>>> cv = ShuffleSplit(n_splits=3, test_size=0.3, random_state=0)
>>> cross_val_score(clf, iris.data, iris.target, cv=cv)
...
array([ 0.97...,  0.97...,  1.        ])
```

## Data transformation with held out data

Just as it is important to test a predictor on data held-out from training, preprocessing (such as standardization, feature selection, etc.) and similar [data transformations](#) similarly should be learnt from a training set and applied to held-out data for prediction:

```
>>> from sklearn import preprocessing
>>> X_train, X_test, y_train, y_test = train_test_split(
...     iris.data, iris.target, test_size=0.4, random_state=0)
>>> scaler = preprocessing.StandardScaler().fit(X_train)
>>> X_train_transformed = scaler.transform(X_train)
>>> clf = svm.SVC(C=1).fit(X_train_transformed, y_train)
>>> X_test_transformed = scaler.transform(X_test)
>>> clf.score(X_test_transformed, y_test)
0.9333...
```

A [Pipeline](#) makes it easier to compose estimators, providing this behavior under cross-validation:

```
>>> from sklearn.pipeline import make_pipeline
>>> clf = make_pipeline(preprocessing.StandardScaler(),
...                      svm.SVC(C=1))
>>> cross_val_score(clf, iris.data, iris.target, cv=cv)
...
array([ 0.97...,  0.93...,  0.95...])
```

See [Pipeline and FeatureUnion: combining estimators](#).

## Obtaining predictions by cross-validation

The function `cross_val_predict` has a similar interface to `cross_val_score`, but returns, for each element in the input, the prediction that was obtained for that element when it was in the test set. Only cross-validation strategies that assign all elements to a test set exactly once can be used (otherwise, an exception is raised).

These prediction can then be used to evaluate the classifier:

```
>>> from sklearn.model_selection import cross_val_predict
>>> predicted = cross_val_predict(clf, iris.data, iris.target, cv=10)
>>> metrics.accuracy_score(iris.target, predicted)
0.966...
```

Note that the result of this computation may be slightly different from those obtained using `cross_val_score` as the elements are grouped in different ways.

The available cross validation iterators are introduced in the following section.

### Examples

- [Receiver Operating Characteristic \(ROC\) with cross validation](#),
- [Recursive feature elimination with cross-validation](#),
- [sphx\\_glr\\_auto\\_examples\\_model\\_selection\\_grid\\_search\\_digits.py](#),
- [Sample pipeline for text feature extraction and evaluation](#),
- [Plotting Cross-Validated Predictions](#),
- [Nested versus non-nested cross-validation](#).

## Cross validation iterators

The following sections list utilities to generate indices that can be used to generate dataset splits according to different cross validation strategies.

### Cross-validation iterators for i.i.d. data

Assuming that some data is Independent Identically Distributed (i.i.d.) is making the assumption that all samples stem from the same generative process and that the generative process is assumed to have no memory of past generated samples.

The following cross-validators can be used in such cases.

#### NOTE

While i.i.d. data is a common assumption in machine learning theory, it rarely holds in practice. If one knows that the samples have been generated using a time-dependent process, it's safer to use a *time-series aware cross-validation scheme* `<time_series_cv>`. Similarly if we know that the generative process has a group structure (samples from collected from different subjects, experiments, measurement devices) it safer to use *group-wise cross-validation* `<group_cv>`.

## K-fold

`KFold` divides all the samples in  $k$  groups of samples, called folds (if  $k = n$ , this is equivalent to the *Leave One Out* strategy), of equal sizes (if possible). The prediction function is learned using  $k - 1$  folds, and the fold left out is used for test.

Example of 2-fold cross-validation on a dataset with 4 samples:

```
>>> import numpy as np
>>> from sklearn.model_selection import KFold

>>> X = ["a", "b", "c", "d"]
>>> kf = KFold(n_splits=2)
>>> for train, test in kf.split(X):
...     print("%s %s" % (train, test))
[2 3] [0 1]
[0 1] [2 3]
```

Each fold is constituted by two arrays: the first one is related to the *training set*, and the second one to the *test set*. Thus, one can create the training/test sets using numpy indexing:

```
>>> X = np.array([[0., 0.], [1., 1.], [-1., -1.], [2., 2.]])
>>> y = np.array([0, 1, 0, 1])
>>> X_train, X_test, y_train, y_test = X[train], X[test], y[train], y[test]
```

## Repeated K-Fold

`RepeatedKFold` repeats K-Fold  $n$  times. It can be used when one requires to run `KFold`  $n$  times, producing different splits in each repetition.

Example of 2-fold K-Fold repeated 2 times:

```
>>> import numpy as np
>>> from sklearn.model_selection import RepeatedKFold
>>> X = np.array([[1, 2], [3, 4], [1, 2], [3, 4]])
>>> random_state = 12883823
>>> rkf = RepeatedKFold(n_splits=2, n_repeats=2, random_state=random_state)
>>> for train, test in rkf.split(X):
...     print("%s %s" % (train, test))
...
[2 3] [0 1]
[0 1] [2 3]
[0 2] [1 3]
[1 3] [0 2]
```

Similarly, `RepeatedStratifiedKFold` repeats Stratified K-Fold  $n$  times with different randomization in each repetition.

## Leave One Out (LOO)

`LeaveOneOut` (or LOO) is a simple cross-validation. Each learning set is created by taking all the samples except one, the test set being the sample left out. Thus, for  $n$  samples, we have  $n$  different training sets and  $n$  different tests set. This cross-validation procedure does not waste much data as only one sample is removed from the training set:

```
>>> from sklearn.model_selection import LeaveOneOut

>>> X = [1, 2, 3, 4]
>>> loo = LeaveOneOut()
>>> for train, test in loo.split(X):
...     print("%s %s" % (train, test))
[1 2 3] [0]
[0 2 3] [1]
[0 1 3] [2]
[0 1 2] [3]
```

Potential users of LOO for model selection should weigh a few known caveats. When compared with  $k$ -fold cross validation, one builds  $n$  models from  $n$  samples instead of  $k$  models, where  $n > k$ . Moreover, each is trained on  $n - 1$  samples rather than  $(k - 1)n/k$ . In both ways, assuming  $k$  is not too large and  $k < n$ , LOO is more computationally expensive than  $k$ -fold cross validation.

In terms of accuracy, LOO often results in high variance as an estimator for the test error. Intuitively, since  $n - 1$  of the  $n$  samples are used to build each model, models constructed from folds are virtually identical to each other and to the model built from the entire training set.

However, if the learning curve is steep for the training size in question, then 5- or 10- fold cross validation can overestimate the generalization error.

As a general rule, most authors, and empirical evidence, suggest that 5- or 10- fold cross validation should be preferred to LOO.

## Leave P Out (LPO)

[LeavePOut](#) is very similar to [LeaveOneOut](#) as it creates all the possible training/test sets by removing  $p$  samples from the complete set. For  $n$  samples, this produces  $\binom{n}{p}$  train-test pairs. Unlike [LeaveOneOut](#) and [KFold](#), the test sets will overlap for  $p > 1$ .

Example of Leave-2-Out on a dataset with 4 samples:

```
>>> from sklearn.model_selection import LeavePOut

>>> X = np.ones(4)
>>> lpo = LeavePOut(p=2)
>>> for train, test in lpo.split(X):
...     print("%s %s" % (train, test))
```

```
[2 3] [0 1]
[1 3] [0 2]
[1 2] [0 3]
[0 3] [1 2]
[0 2] [1 3]
[0 1] [2 3]
```

## Random permutations cross-validation a.k.a. Shuffle & Split

### *ShuffleSplit*

The `ShuffleSplit` iterator will generate a user defined number of independent train / test dataset splits. Samples are first shuffled and then split into a pair of train and test sets.

It is possible to control the randomness for reproducibility of the results by explicitly seeding the `random_state` pseudo random number generator.

Here is a usage example:

```
>>> from sklearn.model_selection import ShuffleSplit
>>> X = np.arange(5)
>>> ss = ShuffleSplit(n_splits=3, test_size=0.25,
...                     random_state=0)
>>> for train_index, test_index in ss.split(X):
...     print("%s %s" % (train_index, test_index))
...
[1 3 4] [2 0]
[1 4 3] [0 2]
[4 0 2] [1 3]
```

`ShuffleSplit` is thus a good alternative to `KFold` cross validation that allows a finer control on the number of iterations and the proportion of samples on each side of the train / test split.

## Cross-validation iterators with stratification based on class labels.

Some classification problems can exhibit a large imbalance in the distribution of the target classes: for instance there could be several times more negative samples than positive samples. In such cases it is recommended to use stratified sampling as implemented in `StratifiedKFold` and `StratifiedShuffleSplit` to ensure that relative class frequencies is approximately preserved in each train and validation fold.

### Stratified k-fold

`StratifiedKFold` is a variation of `k-fold` which returns *stratified* folds: each set contains approximately the same percentage of samples of each target class as the complete set.

Example of stratified 3-fold cross-validation on a dataset with 10 samples from two slightly unbalanced classes:

```
>>> from sklearn.model_selection import StratifiedKFold
>>> X = np.ones(10)
>>> y = [0, 0, 0, 0, 1, 1, 1, 1, 1, 1]
>>> skf = StratifiedKFold(n_splits=3)
>>> for train, test in skf.split(X, y):
...     print("%s %s" % (train, test))
```

```
[2 3 6 7 8 9] [0 1 4 5]
[0 1 3 4 5 8 9] [2 6 7]
[0 1 2 4 5 6 7] [3 8 9]
```

`RepeatedStratifiedKFold` can be used to repeat Stratified K-Fold n times with different randomization in each repetition.

## Stratified Shuffle Split

`StratifiedShuffleSplit` is a variation of `ShuffleSplit`, which returns stratified splits, *i.e* which creates splits by preserving the same percentage for each target class as in the complete set.

## Cross-validation iterators for grouped data.

The i.i.d. assumption is broken if the underlying generative process yield groups of dependent samples.

Such a grouping of data is domain specific. An example would be when there is medical data collected from multiple patients, with multiple samples taken from each patient. And such data is likely to be dependent on the individual group. In our example, the patient id for each sample will be its group identifier.

In this case we would like to know if a model trained on a particular set of groups generalizes well to the unseen groups. To measure this, we need to ensure that all the samples in the validation fold come from groups that are not represented at all in the paired training fold.

The following cross-validation splitters can be used to do that. The grouping identifier for the samples is specified via the `groups` parameter.

## Group k-fold

`class:GroupKFold` is a variation of k-fold which ensures that the same group is not represented in both testing and training sets. For example if the data is obtained from different subjects with several samples per-subject and if the model is flexible enough to learn from highly person specific features it could fail to generalize to new subjects. `class:GroupKFold` makes it possible to detect this kind of overfitting situations.

Imagine you have three subjects, each with an associated number from 1 to 3:

```
>>> from sklearn.model_selection import GroupKFold

>>> X = [0.1, 0.2, 2.2, 2.4, 2.3, 4.55, 5.8, 8.8, 9, 10]
>>> y = ["a", "b", "b", "b", "c", "c", "c", "d", "d", "d"]
>>> groups = [1, 1, 1, 2, 2, 2, 3, 3, 3, 3]

>>> gkf = GroupKFold(n_splits=3)
>>> for train, test in gkf.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
[0 1 2 3 4 5] [6 7 8 9]
[0 1 2 6 7 8 9] [3 4 5]
[3 4 5 6 7 8 9] [0 1 2]
```

Each subject is in a different testing fold, and the same subject is never in both testing and training. Notice that the folds do not have exactly the same size due to the imbalance in the data.

## Leave One Group Out

*LeaveOneGroupOut* is a cross-validation scheme which holds out the samples according to a third-party provided array of integer groups. This group information can be used to encode arbitrary domain specific pre-defined cross-validation folds.

Each training set is thus constituted by all the samples except the ones related to a specific group.

For example, in the cases of multiple experiments, *LeaveOneGroupOut* can be used to create a cross-validation based on the different experiments: we create a training set using the samples of all the experiments except one:

```
>>> from sklearn.model_selection import LeaveOneGroupOut

>>> X = [1, 5, 10, 50, 60, 70, 80]
>>> y = [0, 1, 1, 2, 2, 2, 2]
>>> groups = [1, 1, 2, 2, 3, 3, 3]
>>> logo = LeaveOneGroupOut()
>>> for train, test in logo.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
[2 3 4 5 6] [0 1]
[0 1 4 5 6] [2 3]
[0 1 2 3] [4 5 6]
```

Another common application is to use time information: for instance the groups could be the year of collection of the samples and thus allow for cross-validation against time-based splits.

## Leave P Groups Out

*LeavePGroupsOut* is similar as *LeaveOneGroupOut*, but removes samples related to  $P$  groups for each training/test set.

Example of Leave-2-Group Out:

```
>>> from sklearn.model_selection import LeavePGroupsOut

>>> X = np.arange(6)
>>> y = [1, 1, 1, 2, 2, 2]
>>> groups = [1, 1, 2, 2, 3, 3]
>>> lpg = LeavePGroupsOut(n_groups=2)
>>> for train, test in lpg.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
[4 5] [0 1 2 3]
[2 3] [0 1 4 5]
[0 1] [2 3 4 5]
```

## Group Shuffle Split

*GroupShuffleSplit*

The *GroupShuffleSplit* iterator behaves as a combination of *ShuffleSplit* and *LeavePGroupsOut*, and generates a sequence of randomized partitions in which a subset of groups are held out for each split.

Here is a usage example:

```
>>> from sklearn.model_selection import GroupShuffleSplit
```

```
>>> X = [0.1, 0.2, 2.2, 2.4, 2.3, 4.55, 5.8, 0.001]
>>> y = ["a", "b", "b", "c", "c", "c", "a"]
>>> groups = [1, 1, 2, 2, 3, 3, 4, 4]
>>> gss = GroupShuffleSplit(n_splits=4, test_size=0.5, random_state=0)
>>> for train, test in gss.split(X, y, groups=groups):
...     print("%s %s" % (train, test))
...
[0 1 2 3] [4 5 6 7]
[2 3 6 7] [0 1 4 5]
[2 3 4 5] [0 1 6 7]
[4 5 6 7] [0 1 2 3]
```

This class is useful when the behavior of [LeavePGroupsOut](#) is desired, but the number of groups is large enough that generating all possible partitions with  $P$  groups withheld would be prohibitively expensive. In such a scenario, [GroupShuffleSplit](#) provides a random sample (with replacement) of the train / test splits generated by [LeavePGroupsOut](#).

## Predefined Fold-Splits / Validation-Sets

For some datasets, a pre-defined split of the data into training- and validation fold or into several cross-validation folds already exists. Using [PredefinedSplit](#) it is possible to use these folds e.g. when searching for hyperparameters.

For example, when using a validation set, set the `test_fold` to 0 for all samples that are part of the validation set, and to -1 for all other samples.

## Cross validation of time series data

Time series data is characterised by the correlation between observations that are near in time (*autocorrelation*). However, classical cross-validation techniques such as [KFold](#) and [ShuffleSplit](#) assume the samples are independent and identically distributed, and would result in unreasonable correlation between training and testing instances (yielding poor estimates of generalisation error) on time series data. Therefore, it is very important to evaluate our model for time series data on the “future” observations least like those that are used to train the model. To achieve this, one solution is provided by [TimeSeriesSplit](#).

## Time Series Split

[TimeSeriesSplit](#) is a variation of *k-fold* which returns first  $k$  folds as train set and the  $(k + 1)$  th fold as test set. Note that unlike standard cross-validation methods, successive training sets are supersets of those that come before them. Also, it adds all surplus data to the first training partition, which is always used to train the model.

This class can be used to cross-validate time series data samples that are observed at fixed time intervals.

Example of 3-split time series cross-validation on a dataset with 6 samples:

```
>>> from sklearn.model_selection import TimeSeriesSplit

>>> X = np.array([[1, 2], [3, 4], [1, 2], [3, 4], [1, 2], [3, 4]])
>>> y = np.array([1, 2, 3, 4, 5, 6])
>>> tscv = TimeSeriesSplit(n_splits=3)
>>> print(tscv)
TimeSeriesSplit(n_splits=3)
>>> for train, test in tscv.split(X):
...     print("%s %s" % (train, test))
[0 1 2] [3]
```

```
[0 1 2 3] [4]
[0 1 2 3 4] [5]
```

## A note on shuffling

If the data ordering is not arbitrary (e.g. samples with the same class label are contiguous), shuffling it first may be essential to get a meaningful cross-validation result. However, the opposite may be true if the samples are not independently and identically distributed. For example, if samples correspond to news articles, and are ordered by their time of publication, then shuffling the data will likely lead to a model that is overfit and an inflated validation score: it will be tested on samples that are artificially similar (close in time) to training samples.

Some cross validation iterators, such as `KFold`, have an inbuilt option to shuffle the data indices before splitting them. Note that:

- This consumes less memory than shuffling the data directly.
- By default no shuffling occurs, including for the (stratified) K fold cross-validation performed by specifying `cv=some_integer` to `cross_val_score`, grid search, etc. Keep in mind that `train_test_split` still returns a random split.
- The `random_state` parameter defaults to `None`, meaning that the shuffling will be different every time `KFold(..., shuffle=True)` is iterated. However, `GridSearchCV` will use the same shuffling for each set of parameters validated by a single call to its `fit` method.
- To ensure results are repeatable (*on the same platform*), use a fixed value for `random_state`.

## Cross validation and model selection

Cross validation iterators can also be used to directly perform model selection using Grid Search for the optimal hyperparameters of the model. This is the topic of the next section: *Tuning the hyper-parameters of an estimator*.

### 3.3.2 Tuning the hyper-parameters of an estimator

Hyper-parameters are parameters that are not directly learnt within estimators. In scikit-learn they are passed as arguments to the constructor of the estimator classes. Typical examples include `C`, `kernel` and `gamma` for Support Vector Classifier, `alpha` for Lasso, etc.

It is possible and recommended to search the hyper-parameter space for the best *cross validation* score.

Any parameter provided when constructing an estimator may be optimized in this manner. Specifically, to find the names and current values for all parameters for a given estimator, use:

```
estimator.get_params()
```

A search consists of:

- an estimator (regressor or classifier such as `sklearn.svm.SVC()`);
- a parameter space;
- a method for searching or sampling candidates;
- a cross-validation scheme; and
- a *score function*.

Some models allow for specialized, efficient parameter search strategies, *outlined below*. Two generic approaches to sampling search candidates are provided in scikit-learn: for given values, `GridSearchCV` exhaustively considers all parameter combinations, while `RandomizedSearchCV` can sample a given number of candidates from a parameter space with a specified distribution. After describing these tools we detail *best practice* applicable to both approaches.

Note that it is common that a small subset of those parameters can have a large impact on the predictive or computation performance of the model while others can be left to their default values. It is recommended to read the docstring of the estimator class to get a finer understanding of their expected behavior, possibly by reading the enclosed reference to the literature.

## Exhaustive Grid Search

The grid search provided by `GridSearchCV` exhaustively generates candidates from a grid of parameter values specified with the `param_grid` parameter. For instance, the following `param_grid`:

```
param_grid = [
    {'C': [1, 10, 100, 1000], 'kernel': ['linear']},
    {'C': [1, 10, 100, 1000], 'gamma': [0.001, 0.0001], 'kernel': ['rbf']},
]
```

specifies that two grids should be explored: one with a linear kernel and C values in [1, 10, 100, 1000], and the second one with an RBF kernel, and the cross-product of C values ranging in [1, 10, 100, 1000] and gamma values in [0.001, 0.0001].

The `GridSearchCV` instance implements the usual estimator API: when “fitting” it on a dataset all the possible combinations of parameter values are evaluated and the best combination is retained.

### Examples:

- See `sphx_glr_auto_examples_model_selection_grid_search_digits.py` for an example of Grid Search computation on the digits dataset.
- See [Sample pipeline for text feature extraction and evaluation](#) for an example of Grid Search coupling parameters from a text documents feature extractor (n-gram count vectorizer and TF-IDF transformer) with a classifier (here a linear SVM trained with SGD with either elastic net or L2 penalty) using a pipeline.
- See [Nested versus non-nested cross-validation](#) for an example of Grid Search within a cross validation loop on the iris dataset. This is the best practice for evaluating the performance of a model with grid search.

## Randomized Parameter Optimization

While using a grid of parameter settings is currently the most widely used method for parameter optimization, other search methods have more favourable properties. `RandomizedSearchCV` implements a randomized search over parameters, where each setting is sampled from a distribution over possible parameter values. This has two main benefits over an exhaustive search:

- A budget can be chosen independent of the number of parameters and possible values.
- Adding parameters that do not influence the performance does not decrease efficiency.

Specifying how parameters should be sampled is done using a dictionary, very similar to specifying parameters for `GridSearchCV`. Additionally, a computation budget, being the number of sampled candidates or sampling iterations, is specified using the `n_iter` parameter. For each parameter, either a distribution over possible values or a list of discrete choices (which will be sampled uniformly) can be specified:

```
{'C': scipy.stats.expon(scale=100), 'gamma': scipy.stats.expon(scale=.1),
'kernel': ['rbf'], 'class_weight':['balanced', None]}
```

This example uses the `scipy.stats` module, which contains many useful distributions for sampling parameters, such as `expon`, `gamma`, `uniform` or `randint`. In principle, any function can be passed that provides a `rvs` (random variate sample) method to sample a value. A call to the `rvs` function should provide independent random samples from possible parameter values on consecutive calls.

**Warning:** The distributions in `scipy.stats` prior to version `scipy 0.16` do not allow specifying a random state. Instead, they use the global numpy random state, that can be seeded via `np.random.seed` or set using `np.random.set_state`. However, beginning scikit-learn 0.18, the `sklearn.model_selection` module sets the random state provided by the user if `scipy >= 0.16` is also available.

For continuous parameters, such as `C` above, it is important to specify a continuous distribution to take full advantage of the randomization. This way, increasing `n_iter` will always lead to a finer search.

### Examples:

- `sphx_glr_auto_examples_model_selection_randomized_search.py` compares the usage and efficiency of randomized search and grid search.

- Bergstra, J. and Bengio, Y., Random search for hyper-parameter optimization, *The Journal of Machine Learning Research* (2012)

## Tips for parameter search

### Specifying an objective metric

By default, parameter search uses the `score` function of the estimator to evaluate a parameter setting. These are the `sklearn.metrics.accuracy_score` for classification and `sklearn.metrics.r2_score` for regression. For some applications, other scoring functions are better suited (for example in unbalanced classification, the accuracy score is often uninformative). An alternative scoring function can be specified via the `scoring` parameter to `GridSearchCV`, `RandomizedSearchCV` and many of the specialized cross-validation tools described below. See [The scoring parameter: defining model evaluation rules](#) for more details.

### Composite estimators and parameter spaces

*Pipeline: chaining estimators* describes building composite estimators whose parameter space can be searched with these tools.

## Model selection: development and evaluation

Model selection by evaluating various parameter settings can be seen as a way to use the labeled data to “train” the parameters of the grid.

When evaluating the resulting model it is important to do it on held-out samples that were not seen during the grid search process: it is recommended to split the data into a **development set** (to be fed to the `GridSearchCV` instance) and an **evaluation set** to compute performance metrics.

This can be done by using the `train_test_split` utility function.

## Parallelism

`GridSearchCV` and `RandomizedSearchCV` evaluate each parameter setting independently. Computations can be run in parallel if your OS supports it, by using the keyword `n_jobs=-1`. See function signature for more details.

## Robustness to failure

Some parameter settings may result in a failure to `fit` one or more folds of the data. By default, this will cause the entire search to fail, even if some parameter settings could be fully evaluated. Setting `error_score=0` (or `=np.NaN`) will make the procedure robust to such failure, issuing a warning and setting the score for that fold to 0 (or `Nan`), but completing the search.

## Alternatives to brute force parameter search

### Model specific cross-validation

Some models can fit data for a range of values of some parameter almost as efficiently as fitting the estimator for a single value of the parameter. This feature can be leveraged to perform a more efficient cross-validation used for model selection of this parameter.

The most common parameter amenable to this strategy is the parameter encoding the strength of the regularizer. In this case we say that we compute the **regularization path** of the estimator.

Here is the list of such models:

<code>linear_model.ElasticNetCV([l1_ratio, eps, ...])</code>	Elastic Net model with iterative fitting along a regularization path
<code>linear_model.LarsCV([fit_intercept, ...])</code>	Cross-validated Least Angle Regression model
<code>linear_model.LassoCV([eps, n_alphas, ...])</code>	Lasso linear model with iterative fitting along a regularization path
<code>linear_model.LassoLarsCV([fit_intercept, ...])</code>	Cross-validated Lasso, using the LARS algorithm
<code>linear_model.LogisticRegressionCV([Cs, ...])</code>	Logistic Regression CV (aka logit, MaxEnt) classifier.
<code>linear_model.MultiTaskElasticNetCV(...)</code>	Multi-task L1/L2 ElasticNet with built-in cross-validation.
<code>linear_model.MultiTaskLassoCV(eps, ...)</code>	Multi-task L1/L2 Lasso with built-in cross-validation.
<code>linear_model.OrthogonalMatchingPursuitCV([CROSS-VALIDATED])</code>	Cross-validated Orthogonal Matching Pursuit model (OMP)
<code>linear_model.RidgeCV([alphas, ...])</code>	Ridge regression with built-in cross-validation.
<code>linear_model.RidgeClassifierCV([alphas, ...])</code>	Ridge classifier with built-in cross-validation.

**sklearn.linear\_model.ElasticNetCV**

```
class sklearn.linear_model.ElasticNetCV(l1_ratio=0.5, eps=0.001, n_alphas=100, al-
    phas=None, fit_intercept=True, normalize=False,
    precompute='auto', max_iter=1000, tol=0.0001,
    cv=None, copy_X=True, verbose=0, n_jobs=1, posi-
    tive=False, random_state=None, selection='cyclic')
```

Elastic Net model with iterative fitting along a regularization path

The best model is selected by cross-validation.

Read more in the [User Guide](#).

**Parameters**

**l1\_ratio** : float or array of floats, optional  
 float between 0 and 1 passed to ElasticNet (scaling between l1 and l2 penalties). For `l1_ratio = 0` the penalty is an L2 penalty. For `l1_ratio = 1` it is an L1 penalty. For  $0 < l1\_ratio < 1$ , the penalty is a combination of L1 and L2. This parameter can be a list, in which case the different values are tested by cross-validation and the one giving the best prediction score is used. Note that a good choice of list of values for `l1_ratio` is often to put more values close to 1 (i.e. Lasso) and less close to 0 (i.e. Ridge), as in `[.1, .5, .7, .9, .95, .99, 1]`

**eps** : float, optional

Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`.

**n\_alphas** : int, optional

Number of alphas along the regularization path, used for each `l1_ratio`.

**alphas** : numpy array, optional

List of alphas where to compute the models. If None alphas are set automatically

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**max\_iter** : int, optional

The maximum number of iterations

**tol** : float, optional

The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for `cv` are:

- None, to use the default 3-fold cross-validation,
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/None inputs, `KFold` is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**verbose** : bool or integer

Amount of verbosity.

**n\_jobs** : integer, optional

Number of CPUs to use during the cross validation. If `-1`, use all the CPUs.

**positive** : bool, optional

When set to `True`, forces the coefficients to be positive.

**selection** : str, default ‘cyclic’

If set to ‘random’, a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to ‘random’) often leads to significantly faster convergence especially when `tol` is higher than `1e-4`.

**random\_state** : int, RandomState instance or None, optional, default `None`

The seed of the pseudo random number generator that selects a random feature to update. If int, `random_state` is the seed used by the random number generator; If `RandomState` instance, `random_state` is the random number generator; If `None`, the random number generator is the `RandomState` instance used by `np.random`. Used when `selection == 'random'`.

**fit\_intercept** : boolean

whether to calculate the intercept for this model. If set to `false`, no intercept will be used in calculations (e.g. data is expected to be already centered).

**normalize** : boolean, optional, default `False`

This parameter is ignored when `fit_intercept` is set to `False`. If `True`, the regressors `X` will be normalized before regression by subtracting the mean and dividing by the `l2`-norm. If you wish to standardize, please use `sklearn.preprocessing.StandardScaler` before calling `fit` on an estimator with `normalize=False`.

**copy\_X** : boolean, optional, default `True`

If `True`, `X` will be copied; else, it may be overwritten.

**Attributes** `alpha_` : float

The amount of penalization chosen by cross validation

`l1_ratio` : float

The compromise between `l1` and `l2` penalization chosen by cross validation

`coef_` : array, shape (`n_features`,) | (`n_targets`, `n_features`)

Parameter vector (`w` in the cost function formula),

`intercept_` : float | array, shape (`n_targets`, `n_features`)

Independent term in the decision function.

`mse_path_` : array, shape (`n_l1_ratio`, `n_alpha`, `n_folds`)

Mean square error for the test set on each fold, varying `l1_ratio` and `alpha`.

`alphas_` : numpy array, shape (`n_alphas`,) or (`n_l1_ratio`, `n_alphas`)

The grid of alphas used for fitting, for each `l1_ratio`.

`n_iter_` : int

number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

**See also:**

`enet_path`, `ElasticNet`

**Notes**

See examples/linear\_model/plot\_lasso\_model\_selection.py for an example.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

The parameter l1\_ratio corresponds to alpha in the glmnet R package while alpha corresponds to the lambda parameter in glmnet. More specifically, the optimization objective is:

```
1 / (2 * n_samples) * ||y - Xw||^2_2
+ alpha * l1_ratio * ||w||_1
+ 0.5 * alpha * (1 - l1_ratio) * ||w||^2_2
```

If you are interested in controlling the L1 and L2 penalty separately, keep in mind that this is equivalent to:

```
a * L1 + b * L2
```

for:

```
alpha = a + b and l1_ratio = a / (a + b).
```

**Methods**

<code>fit(X, y)</code>	Fit linear model with coordinate descent
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>path(X, y[, l1_ratio, eps, n_alphas, ...])</code>	Compute elastic net path with coordinate descent
<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

```
__init__(l1_ratio=0.5, eps=0.001, n_alphas=100, alphas=None, fit_intercept=True, normalize=False, precompute='auto', max_iter=1000, tol=0.0001, cv=None, copy_X=True, verbose=0, n_jobs=1, positive=False, random_state=None, selection='cyclic')
```

`fit(X, y)`

Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

**Parameters** `X` : {array-like}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If y is mono-output, X can be sparse.

`y` : array-like, shape (n\_samples,) or (n\_samples, n\_targets)

Target values

`get_params(deep=True)`

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** `params` : mapping of string to any

Parameter names mapped to their values.

```
static path(X, y, l1_ratio=0.5, eps=0.001, n_alphas=100, alphas=None, precompute='auto',
           Xy=None, copy_X=True, coef_init=None, verbose=False, return_n_iter=False, positive=False,
           check_input=True, **params)
```

Compute elastic net path with coordinate descent

The elastic net optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
1 / (2 * n_samples) * ||y - Xw||^2_2
+ alpha * l1_ratio * ||w||_1
+ 0.5 * alpha * (1 - l1_ratio) * ||w||^2_2
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^Fro_2
+ alpha * l1_ratio * ||W||_21
+ 0.5 * alpha * (1 - l1_ratio) * ||W||_Fro^2
```

Where:

$$\|W\|_{21} = \sum_i \sqrt{\sum_j w_{ij}^2}$$

i.e. the sum of norm of each row.

Read more in the [User Guide](#).

**Parameters** `X` : {array-like}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If `y` is mono-output then `X` can be sparse.

`y` : ndarray, shape (n\_samples,) or (n\_samples, n\_outputs)

Target values

`l1_ratio` : float, optional

float between 0 and 1 passed to elastic net (scaling between 11 and 12 penalties). `l1_ratio=1` corresponds to the Lasso

`eps` : float

Length of the path. `eps=1e-3` means that `alpha_min / alpha_max = 1e-3`

`n_alphas` : int, optional

Number of alphas along the regularization path

`alphas` : ndarray, optional

List of alphas where to compute the models. If None alphas are set automatically

`precompute` : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**Xy** : array-like, optional

$Xy = np.dot(X.T, y)$  that can be precomputed. It is useful only when the Gram matrix is precomputed.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**coef\_init** : array, shape (n\_features,) | None

The initial values of the coefficients.

**verbose** : bool or integer

Amount of verbosity.

**params** : kwargs

keyword arguments passed to the coordinate descent solver.

**return\_n\_iter** : bool

whether to return the number of iterations or not.

**positive** : bool, default False

If set to True, forces coefficients to be positive. (Only allowed when  $y.ndim == 1$ ).

**check\_input** : bool, default True

Skip input validation checks, including the Gram matrix when provided assuming there are handled by the caller when `check_input=False`.

**Returns** **alphas** : array, shape (n\_alphas,)

The alphas along the path where models are computed.

**coefs** : array, shape (n\_features, n\_alphas) or (n\_outputs, n\_features, n\_alphas)

Coefficients along the path.

**dual\_gaps** : array, shape (n\_alphas,)

The dual gaps at the end of the optimization for each alpha.

**n\_iters** : array-like, shape (n\_alphas,)

The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha. (Is returned when `return_n_iter` is set to True).

## Notes

See examples/linear\_model/plot\_lasso\_coordinate\_descent\_path.py for an example.

**predict** ( $X$ )

Predict using the linear model

**Parameters**  $X$  : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns**  $C$  : array, shape = (n\_samples,)

Returns predicted values.

**score** (*X*, *y*, *sample\_weight=None*)

Returns the coefficient of determination R<sup>2</sup> of the prediction.

The coefficient R<sup>2</sup> is defined as  $(1 - u/v)$ , where *u* is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and *v* is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of *y*, disregarding the input features, would get a R<sup>2</sup> score of 0.0.

**Parameters** *X* : array-like, shape = (n\_samples, n\_features)

Test samples.

*y* : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for *X*.

*sample\_weight* : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** *score* : float

R<sup>2</sup> of self.predict(*X*) wrt. *y*.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** *self* :

## sklearn.linear\_model.LarsCV

```
class sklearn.linear_model.LarsCV(fit_intercept=True, verbose=False, max_iter=500, normalize=True, precompute='auto', cv=None, max_n_alphas=1000, n_jobs=1, eps=2.220446049250313e-16, copy_X=True, positive=False)
```

Cross-validated Least Angle Regression model

Read more in the [User Guide](#).

**Parameters** *fit\_intercept* : boolean

whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

**positive** : boolean (default=False)

Restrict coefficients to be  $\geq 0$ . Be aware that you might want to remove *fit\_intercept* which is set True by default.

**verbose** : boolean or integer, optional

Sets the verbosity amount

**normalize** : boolean, optional, default True

This parameter is ignored when *fit\_intercept* is set to False. If True, the regressors *X* will be normalized before regression by subtracting the mean and dividing by

the l2-norm. If you wish to standardize, please use `sklearn.preprocessing.StandardScaler` before calling `fit` on an estimator with `normalize=False`.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**max\_iter** : integer, optional

Maximum number of iterations to perform.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 3-fold cross-validation,
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/None inputs, KFold is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**max\_n\_alphas** : integer, optional

The maximum number of points on the path used to compute the residuals in the cross-validation

**n\_jobs** : integer, optional

Number of CPUs to use during the cross validation. If -1, use all the CPUs

**eps** : float, optional

The machine-precision regularization in the computation of the Cholesky diagonal factors. Increase this for very ill-conditioned systems.

**Attributes** **coef\_** : array, shape (n\_features,)

parameter vector (w in the formulation formula)

**intercept\_** : float

independent term in decision function

**coef\_path\_** : array, shape (n\_features, n\_alphas)

the varying values of the coefficients along the path

**alpha\_** : float

the estimated regularization parameter alpha

**alphas\_** : array, shape (n\_alphas,)

the different values of alpha along the path

**cv\_alphas\_** : array, shape (n\_cv\_alphas,)

all the values of alpha along the path for the different folds

**`mse_path_`** : array, shape (n\_folds, n\_cv\_alphas)  
the mean square error on left-out for each fold along the path (alpha values given by `cv_alphas`)  
**`n_iter_`** : array-like or int  
the number of iterations run by Lars with the optimal alpha.

**See also:**

`lars_path`, `LassoLars`, `LassoLarsCV`

## Methods

<code>fit(X, y)</code>	Fit the model using X, y as training data.
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

**`__init__(fit_intercept=True, verbose=False, max_iter=500, normalize=True, precompute='auto', cv=None, max_n_alphas=1000, n_jobs=1, eps=2.2204460492503131e-16, copy_X=True, positive=False)`**  
DEPRECATED: Attribute `cv_mse_path_` is deprecated in 0.18 and will be removed in 0.20. Use '`mse_path_`' instead

**`cv_mse_path_`**  
Fit the model using X, y as training data.

**Parameters** `X` : array-like, shape (n\_samples, n\_features)  
Training data.  
`y` : array-like, shape (n\_samples,)  
Target values.

**Returns** `self` : object  
returns an instance of self.

**`get_params(deep=True)`**  
Get parameters for this estimator.

**Parameters** `deep` : boolean, optional  
If True, will return the parameters for this estimator and contained subobjects that are estimators.

**`Returns` `params`** : mapping of string to any  
Parameter names mapped to their values.

**`predict(X)`**  
Predict using the linear model

**Parameters** `X` : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** **C** : array, shape = (n\_samples,)

Returns predicted values.

**score** (X, y, sample\_weight=None)

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - \frac{u}{v})$ , where u is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and v is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

**Parameters** **X** : array-like, shape = (n\_samples, n\_features)

Test samples.

**y** : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for X.

**sample\_weight** : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** **score** : float

R^2 of self.predict(X) wrt. y.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** **self** :

## sklearn.linear\_model.LassoCV

```
class sklearn.linear_model.LassoCV(eps=0.001, n_alphas=100, alphas=None, fit_intercept=True,
                                    normalize=False, precompute='auto', max_iter=1000,
                                    tol=0.0001, copy_X=True, cv=None, verbose=False,
                                    n_jobs=1, positive=False, random_state=None, selection='cyclic')
```

Lasso linear model with iterative fitting along a regularization path

The best model is selected by cross-validation.

The optimization objective for Lasso is:

$$(\frac{1}{2} * n_{samples}) * ||y - Xw||^2 + alpha * ||w||_1$$

Read more in the *User Guide*.

**Parameters** **eps** : float, optional

Length of the path. eps=1e-3 means that alpha\_min / alpha\_max = 1e-3.

**n\_alphas** : int, optional

Number of alphas along the regularization path

**alphas** : numpy array, optional

List of alphas where to compute the models. If `None` alphas are set automatically

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**max\_iter** : int, optional

The maximum number of iterations

**tol** : float, optional

The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for `cv` are:

- `None`, to use the default 3-fold cross-validation,
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/`None` inputs, `KFold` is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**verbose** : bool or integer

Amount of verbosity.

**n\_jobs** : integer, optional

Number of CPUs to use during the cross validation. If `-1`, use all the CPUs.

**positive** : bool, optional

If positive, restrict regression coefficients to be positive

**selection** : str, default ‘cyclic’

If set to ‘random’, a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to ‘random’) often leads to significantly faster convergence especially when `tol` is higher than `1e-4`.

**random\_state** : int, RandomState instance or `None`, optional, default `None`

The seed of the pseudo random number generator that selects a random feature to update. If int, `random_state` is the seed used by the random number generator; If `RandomState` instance, `random_state` is the random number generator; If `None`, the random number generator is the `RandomState` instance used by `np.random`. Used when `selection == ‘random’`.

**fit\_intercept** : boolean, default `True`

whether to calculate the intercept for this model. If set to `false`, no intercept will be used in calculations (e.g. data is expected to be already centered).

**normalize** : boolean, optional, default `False`

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use `sklearn.preprocessing.StandardScaler` before calling `fit` on an estimator with `normalize=False`.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**Attributes** `alpha_` : float

The amount of penalization chosen by cross validation

`coef_` : array, shape (n\_features,) | (n\_targets, n\_features)

parameter vector (w in the cost function formula)

`intercept_` : float | array, shape (n\_targets,)

independent term in decision function.

`mse_path_` : array, shape (n\_alphas, n\_folds)

mean square error for the test set on each fold, varying alpha

`alphas_` : numpy array, shape (n\_alphas,)

The grid of alphas used for fitting

`dual_gap_` : ndarray, shape ()

The dual gap at the end of the optimization for the optimal alpha (`alpha_`).

`n_iter_` : int

number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

## See also:

`lars_path`, `lasso_path`, `LassoLars`, `Lasso`, `LassoLarsCV`

## Notes

See examples/linear\_model/plot\_lasso\_model\_selection.py for an example.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

## Methods

<code>fit(X, y)</code>	Fit linear model with coordinate descent
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>path(X, y[, eps, n_alphas, alphas, ...])</code>	Compute Lasso path with coordinate descent
<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

**\_\_init\_\_(***eps=0.001, n\_alphas=100, alphas=None, fit\_intercept=True, normalize=False, precompute='auto', max\_iter=1000, tol=0.0001, copy\_X=True, cv=None, verbose=False, n\_jobs=1, positive=False, random\_state=None, selection='cyclic')*

**fit(***X, y*)

Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

**Parameters X :** {array-like}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If *y* is mono-output, *X* can be sparse.

**y :** array-like, shape (n\_samples,) or (n\_samples, n\_targets)

Target values

**get\_params(deep=True)**

Get parameters for this estimator.

**Parameters deep :** boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns params :** mapping of string to any

Parameter names mapped to their values.

**static path(***X, y, eps=0.001, n\_alphas=100, alphas=None, precompute='auto', Xy=None, copy\_X=True, coef\_init=None, verbose=False, return\_n\_iter=False, positive=False, \*\*params)*

Compute Lasso path with coordinate descent

The Lasso optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
(1 / (2 * n_samples)) * ||y - Xw||^2 + alpha * ||w||_1
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^2_Fro + alpha * ||W||_21
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the [User Guide](#).

**Parameters X :** {array-like, sparse matrix}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If *y* is mono-output then *X* can be sparse.

**y :** ndarray, shape (n\_samples,), or (n\_samples, n\_outputs)

Target values

**eps :** float, optional

Length of the path. *eps*=1e-3 means that *alpha\_min* / *alpha\_max* = 1e-3

**n\_alphas** : int, optional

Number of alphas along the regularization path

**alphas** : ndarray, optional

List of alphas where to compute the models. If `None` alphas are set automatically

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**Xy** : array-like, optional

$Xy = np.dot(X.T, y)$  that can be precomputed. It is useful only when the Gram matrix is precomputed.

**copy\_X** : boolean, optional, default True

If `True`,  $X$  will be copied; else, it may be overwritten.

**coef\_init** : array, shape (n\_features,) | `None`

The initial values of the coefficients.

**verbose** : bool or integer

Amount of verbosity.

**params** : kwargs

keyword arguments passed to the coordinate descent solver.

**positive** : bool, default False

If set to `True`, forces coefficients to be positive. (Only allowed when  $y$ .ndim == 1).

**return\_n\_iter** : bool

whether to return the number of iterations or not.

**Returns** **alphas** : array, shape (n\_alphas,)

The alphas along the path where models are computed.

**coefs** : array, shape (n\_features, n\_alphas) or (n\_outputs, n\_features, n\_alphas)

Coefficients along the path.

**dual\_gaps** : array, shape (n\_alphas,)

The dual gaps at the end of the optimization for each alpha.

**n\_iters** : array-like, shape (n\_alphas,)

The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha.

**See also:**

`lars_path`, `Lasso`, `LassoLars`, `LassoCV`, `LassoLarsCV`, `sklearn.decomposition.sparse_encode`

## Notes

See examples/linear\_model/plot\_lasso\_coordinate\_descent\_path.py for an example.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

Note that in certain cases, the Lars solver may be significantly faster to implement this functionality. In particular, linear interpolation can be used to retrieve model coefficients between the values output by lars\_path

## Examples

Comparing lasso\_path and lars\_path with interpolation:

```
>>> X = np.array([[1, 2, 3.1], [2.3, 5.4, 4.3]]).T
>>> y = np.array([1, 2, 3.1])
>>> # Use lasso_path to compute a coefficient path
>>> _, coef_path, _ = lasso_path(X, y, alphas=[5., 1., .5])
>>> print(coef_path)
[[ 0.          0.          0.46874778]
 [ 0.2159048  0.4425765  0.23689075]]
```

```
>>> # Now use lars_path and 1D linear interpolation to compute the
>>> # same path
>>> from sklearn.linear_model import lars_path
>>> alphas, active, coef_path_lars = lars_path(X, y, method='lasso')
>>> from scipy import interpolate
>>> coef_path_continuous = interpolate.interp1d(alphas[::-1],
...                                              coef_path_lars[:, ::-1])
>>> print(coef_path_continuous([5., 1., .5]))
[[ 0.          0.          0.46915237]
 [ 0.2159048  0.4425765  0.23668876]]
```

### `predict(X)`

Predict using the linear model

**Parameters** `X` : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** `C` : array, shape = (n\_samples,)

Returns predicted values.

### `score(X, y, sample_weight=None)`

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - u/v)$ , where u is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and v is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

**Parameters** `X` : array-like, shape = (n\_samples, n\_features)

Test samples.

`y` : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for X.

**sample\_weight** : array-like, shape = [n\_samples], optional

Sample weights.

**Returns score** : float

$R^2$  of self.predict(X) wrt. y.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns self** :

## Examples using `sklearn.linear_model.LassoCV`

- *Cross-validation on diabetes Dataset Exercise*
- *Feature selection using SelectFromModel and LassoCV*
- *Lasso model selection: Cross-Validation / AIC / BIC*

## sklearn.linear\_model.LassoLarsCV

```
class sklearn.linear_model.LassoLarsCV(fit_intercept=True, verbose=False, max_iter=500,
                                         normalize=True, precompute='auto',
                                         cv=None, max_n_alphas=1000, n_jobs=1,
                                         eps=2.2204460492503131e-16, copy_X=True, positive=False)
```

Cross-validated Lasso, using the LARS algorithm

The optimization objective for Lasso is:

$$(1 / (2 * n\_samples)) * ||y - Xw||^2_2 + \alpha * ||w||_1$$

Read more in the *User Guide*.

**Parameters** `fit_intercept` : boolean

whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

`positive` : boolean (default=False)

Restrict coefficients to be  $\geq 0$ . Be aware that you might want to remove `fit_intercept` which is set True by default. Under the positive restriction the model coefficients do not converge to the ordinary-least-squares solution for small values of alpha. Only coefficients up to the smallest alpha value (`alphas_[alphas_ > 0.].min()` when `fit_path=True`) reached by the stepwise Lars-Lasso algorithm are typically in congruence with the solution of the coordinate descent Lasso estimator. As a consequence using LassoLarsCV only makes sense for problems where a sparse solution is expected and/or reached.

`verbose` : boolean or integer, optional

Sets the verbosity amount

**normalize** : boolean, optional, default True

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use `sklearn.preprocessing.StandardScaler` before calling `fit` on an estimator with `normalize=False`.

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**max\_iter** : integer, optional

Maximum number of iterations to perform.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 3-fold cross-validation,
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/None inputs, `KFold` is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**max\_n\_alphas** : integer, optional

The maximum number of points on the path used to compute the residuals in the cross-validation

**n\_jobs** : integer, optional

Number of CPUs to use during the cross validation. If -1, use all the CPUs

**eps** : float, optional

The machine-precision regularization in the computation of the Cholesky diagonal factors. Increase this for very ill-conditioned systems.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**Attributes** **coef\_** : array, shape (n\_features,)

parameter vector (w in the formulation formula)

**intercept\_** : float

independent term in decision function.

**coef\_path\_** : array, shape (n\_features, n\_alphas)

the varying values of the coefficients along the path

**alpha\_** : float

the estimated regularization parameter alpha

**alphas\_** : array, shape (n\_alphas,)

the different values of alpha along the path

**cv\_alphas\_** : array, shape (n\_cv\_alphas,)  
     all the values of alpha along the path for the different folds

**mse\_path\_** : array, shape (n\_folds, n\_cv\_alphas)  
     the mean square error on left-out for each fold along the path (alpha values given by cv\_alphas)

**n\_iter\_** : array-like or int  
     the number of iterations run by Lars with the optimal alpha.

**See also:**

[lars\\_path](#), [LassoLars](#), [LarsCV](#), [LassoCV](#)

**Notes**

The object solves the same problem as the LassoCV object. However, unlike the LassoCV, it find the relevant alphas values by itself. In general, because of this property, it will be more stable. However, it is more fragile to heavily multicollinear datasets.

It is more efficient than the LassoCV if only a small number of features are selected compared to the total number, for instance if there are very few samples compared to the number of features.

**Methods**

<code>fit(X, y)</code>	Fit the model using X, y as training data.
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

**\_\_init\_\_** (`fit_intercept=True`, `verbose=False`, `max_iter=500`, `normalize=True`, `precompute='auto'`,  
`cv=None`, `max_n_alphas=1000`, `n_jobs=1`, `eps=2.2204460492503131e-16`, `copy_X=True`,  
`positive=False`)

**cv\_mse\_path\_**  
 DEPRECATED: Attribute `cv_mse_path_` is deprecated in 0.18 and will be removed in 0.20. Use '`mse_path_`' instead

**fit** (`X, y`)  
 Fit the model using X, y as training data.

**Parameters** `X` : array-like, shape (n\_samples, n\_features)  
 Training data.  
`y` : array-like, shape (n\_samples,)  
 Target values.

**Returns** `self` : object  
 returns an instance of self.

**get\_params**(*deep=True*)

Get parameters for this estimator.

**Parameters** *deep* : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** *params* : mapping of string to any

Parameter names mapped to their values.

**predict**(*X*)

Predict using the linear model

**Parameters** *X* : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** *C* : array, shape = (n\_samples,)

Returns predicted values.

**score**(*X*, *y*, *sample\_weight=None*)

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - u/v)$ , where  $u$  is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and  $v$  is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of  $y$ , disregarding the input features, would get a R^2 score of 0.0.

**Parameters** *X* : array-like, shape = (n\_samples, n\_features)

Test samples.

*y* : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for *X*.

*sample\_weight* : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** *score* : float

R^2 of self.predict(*X*) wrt. *y*.

**set\_params**(\**params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** *self* :

## Examples using `sklearn.linear_model.LassoLarsCV`

- *Lasso model selection: Cross-Validation / AIC / BIC*
- *Sparse recovery: feature selection for sparse linear models*

**`sklearn.linear_model.LogisticRegressionCV`**

```
class sklearn.linear_model.LogisticRegressionCV(Cs=10, fit_intercept=True, cv=None,
                                              dual=False, penalty='l2', scoring=None,
                                              solver='lbfgs', tol=0.0001,
                                              max_iter=100, class_weight=None,
                                              n_jobs=1, verbose=0, refit=True, intercept_scaling=1.0,
                                              multi_class='ovr', random_state=None)
```

Logistic Regression CV (aka logit, MaxEnt) classifier.

This class implements logistic regression using liblinear, newton-cg, sag or lbfgs optimizer. The newton-cg, sag and lbfgs solvers support only L2 regularization with primal formulation. The liblinear solver supports both L1 and L2 regularization, with a dual formulation only for the L2 penalty.

For the grid of Cs values (that are set by default to be ten values in a logarithmic scale between 1e-4 and 1e4), the best hyperparameter is selected by the cross-validator StratifiedKFold, but it can be changed using the cv parameter. In the case of newton-cg and lbfgs solvers, we warm start along the path i.e guess the initial coefficients of the present fit to be the coefficients got after convergence in the previous fit, so it is supposed to be faster for high-dimensional dense data.

For a multiclass problem, the hyperparameters for each class are computed using the best scores got by doing a one-vs-rest in parallel across all folds and classes. Hence this is not the true multinomial loss.

Read more in the [User Guide](#).

**Parameters**

**Cs** : list of floats | int

Each of the values in Cs describes the inverse of regularization strength. If Cs is as an int, then a grid of Cs values are chosen in a logarithmic scale between 1e-4 and 1e4. Like in support vector machines, smaller values specify stronger regularization.

**fit\_intercept** : bool, default: True

Specifies if a constant (a.k.a. bias or intercept) should be added to the decision function.

**class\_weight** : dict or ‘balanced’, optional

Weights associated with classes in the form {class\_label: weight}. If not given, all classes are supposed to have weight one.

The “balanced” mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as n\_samples / (n\_classes \* np.bincount(y)).

Note that these weights will be multiplied with sample\_weight (passed through the fit method) if sample\_weight is specified.

New in version 0.17: class\_weight == ‘balanced’

**cv** : integer or cross-validation generator

The default cross-validation generator used is Stratified K-Folds. If an integer is provided, then it is the number of folds used. See the module [sklearn.model\\_selection](#) module for the list of possible cross-validation objects.

**penalty** : str, ‘l1’ or ‘l2’

Used to specify the norm used in the penalization. The ‘newton-cg’, ‘sag’ and ‘lbfgs’ solvers support only l2 penalties.

**dual** : bool

Dual or primal formulation. Dual formulation is only implemented for l2 penalty with liblinear solver. Prefer dual=False when n\_samples > n\_features.

**scoring** : string, callable, or None

A string (see model evaluation documentation) or a scorer callable object / function with signature `scorer(estimator, X, y)`. For a list of scoring functions that can be used, look at `sklearn.metrics`. The default scoring option used is ‘accuracy’.

**solver** : {‘newton-cg’, ‘lbfgs’, ‘liblinear’, ‘sag’, ‘saga’},

default: ‘liblinear’ Algorithm to use in the optimization problem.

- **For small datasets, ‘liblinear’ is a good choice, whereas ‘sag’ and ‘saga’ are faster for large ones.**
- **For multiclass problems, only ‘newton-cg’, ‘sag’, ‘saga’ and ‘lbfgs’ handle multinomial loss; ‘liblinear’ is limited to one-versus-rest schemes.**
- **‘newton-cg’, ‘lbfgs’ and ‘sag’ only handle L2 penalty, whereas ‘liblinear’ and ‘saga’ handle L1 penalty.**
- **‘liblinear’ might be slower in LogisticRegressionCV because it does not handle warm-starting.**

Note that ‘sag’ and ‘saga’ fast convergence is only guaranteed on features with approximately the same scale. You can preprocess the data with a scaler from `sklearn.preprocessing`.

New in version 0.17: Stochastic Average Gradient descent solver.

New in version 0.19: SAGA solver.

**tol** : float, optional

Tolerance for stopping criteria.

**max\_iter** : int, optional

Maximum number of iterations of the optimization algorithm.

**n\_jobs** : int, optional

Number of CPU cores used during the cross-validation loop. If given a value of -1, all cores are used.

**verbose** : int

For the ‘liblinear’, ‘sag’ and ‘lbfgs’ solvers set verbose to any positive number for verbosity.

**refit** : bool

If set to True, the scores are averaged across all folds, and the coefs and the C that corresponds to the best score is taken, and a final refit is done using these parameters. Otherwise the coefs, intercepts and C that correspond to the best scores across folds are averaged.

**multi\_class** : str, {‘ovr’, ‘multinomial’}

Multiclass option can be either ‘ovr’ or ‘multinomial’. If the option chosen is ‘ovr’, then a binary problem is fit for each label. Else the loss minimised is the multinomial loss fit across the entire probability distribution. Works only for the ‘newton-cg’, ‘sag’ and ‘lbfgs’ solver.

New in version 0.18: Stochastic Average Gradient descent solver for ‘multinomial’ case.

**intercept\_scaling** : float, default 1.

Useful only when the solver ‘liblinear’ is used and self.fit\_intercept is set to True. In this case, x becomes [x, self.intercept\_scaling], i.e. a “synthetic” feature with constant value equal to intercept\_scaling is appended to the instance vector. The intercept becomes intercept\_scaling \* synthetic\_feature\_weight.

Note! the synthetic feature weight is subject to l1/l2 regularization as all other features. To lessen the effect of regularization on synthetic feature weight (and therefore on the intercept) intercept\_scaling has to be increased.

**random\_state** : int, RandomState instance or None, optional, default None

If int, random\_state is the seed used by the random number generator; If RandomState instance, random\_state is the random number generator; If None, the random number generator is the RandomState instance used by *np.random*.

**Attributes** **coef\_** : array, shape (1, n\_features) or (n\_classes, n\_features)

Coefficient of the features in the decision function.

*coef\_* is of shape (1, n\_features) when the given problem is binary.

**intercept\_** : array, shape (1,) or (n\_classes,)

Intercept (a.k.a. bias) added to the decision function.

If *fit\_intercept* is set to False, the intercept is set to zero. *intercept\_* is of shape(1,) when the problem is binary.

**Cs\_** : array

Array of C i.e. inverse of regularization parameter values used for cross-validation.

**coefs\_paths\_** : array, shape (n\_folds, len(Cs\_), n\_features) or (n\_folds, len(Cs\_), n\_features + 1)

dict with classes as the keys, and the path of coefficients obtained during cross-validating across each fold and then across each Cs after doing an OvR for the corresponding class as values. If the ‘multi\_class’ option is set to ‘multinomial’, then the coefs\_paths are the coefficients corresponding to each class. Each dict value has shape (n\_folds, len(Cs\_), n\_features) or (n\_folds, len(Cs\_), n\_features + 1) depending on whether the intercept is fit or not.

**scores\_** : dict

dict with classes as the keys, and the values as the grid of scores obtained during cross-validating each fold, after doing an OvR for the corresponding class. If the ‘multi\_class’ option given is ‘multinomial’ then the same scores are repeated across all classes, since this is the multinomial class. Each dict value has shape (n\_folds, len(Cs))

**C\_** : array, shape (n\_classes,) or (n\_classes - 1,)

Array of C that maps to the best scores across every class. If refit is set to False, then for each class, the best C is the average of the C’s that correspond to the best scores for each fold. *C\_* is of shape(n\_classes,) when the problem is binary.

**n\_iter\_** : array, shape (n\_classes, n\_folds, n\_cs) or (1, n\_folds, n\_cs)

Actual number of iterations for all classes, folds and Cs. In the binary or multinomial cases, the first dimension is equal to 1.

**See also:**

[LogisticRegression](#)

**Methods**

<code>decision_function(X)</code>	Predict confidence scores for samples.
<code>densify()</code>	Convert coefficient matrix to dense array format.
<code>fit(X, y[, sample_weight])</code>	Fit the model according to the given training data.
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict class labels for samples in X.
<code>predict_log_proba(X)</code>	Log of probability estimates.
<code>predict_proba(X)</code>	Probability estimates.
<code>score(X, y[, sample_weight])</code>	Returns the mean accuracy on the given test data and labels.
<code>set_params(**params)</code>	Set the parameters of this estimator.
<code>sparsify()</code>	Convert coefficient matrix to sparse format.

`__init__(Cs=10, fit_intercept=True, cv=None, dual=False, penalty='l2', scoring=None, solver='lbfgs', tol=0.0001, max_iter=100, class_weight=None, n_jobs=1, verbose=0, refit=True, intercept_scaling=1.0, multi_class='ovr', random_state=None)`

**`decision_function(X)`**

Predict confidence scores for samples.

The confidence score for a sample is the signed distance of that sample to the hyperplane.

**Parameters** `X` : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** `array, shape=(n_samples,) if n_classes == 2 else (n_samples, n_classes) :`

Confidence scores per (sample, class) combination. In the binary case, confidence score for self.classes\_[1] where >0 means this class would be predicted.

**`densify()`**

Convert coefficient matrix to dense array format.

Converts the `coef_` member (back) to a numpy.ndarray. This is the default format of `coef_` and is required for fitting, so calling this method is only required on models that have previously been sparsified; otherwise, it is a no-op.

**Returns** `self` : estimator

**`fit(X, y, sample_weight=None)`**

Fit the model according to the given training data.

**Parameters** `X` : {array-like, sparse matrix}, shape (n\_samples, n\_features)

Training vector, where n\_samples is the number of samples and n\_features is the number of features.

`y` : array-like, shape (n\_samples,)

Target vector relative to X.

`sample_weight` : array-like, shape (n\_samples,) optional

Array of weights that are assigned to individual samples. If not provided, then each sample is given unit weight.

**Returns self** : object

Returns self.

**get\_params (deep=True)**

Get parameters for this estimator.

**Parameters deep** : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns params** : mapping of string to any

Parameter names mapped to their values.

**predict (X)**

Predict class labels for samples in X.

**Parameters X** : {array-like, sparse matrix}, shape = [n\_samples, n\_features]

Samples.

**Returns C** : array, shape = [n\_samples]

Predicted class label per sample.

**predict\_log\_proba (X)**

Log of probability estimates.

The returned estimates for all classes are ordered by the label of classes.

**Parameters X** : array-like, shape = [n\_samples, n\_features]

**Returns T** : array-like, shape = [n\_samples, n\_classes]

Returns the log-probability of the sample for each class in the model, where classes are ordered as they are in `self.classes_`.

**predict\_proba (X)**

Probability estimates.

The returned estimates for all classes are ordered by the label of classes.

For a multi\_class problem, if `multi_class` is set to be “multinomial” the softmax function is used to find the predicted probability of each class. Else use a one-vs-rest approach, i.e calculate the probability of each class assuming it to be positive using the logistic function. and normalize these values across all the classes.

**Parameters X** : array-like, shape = [n\_samples, n\_features]

**Returns T** : array-like, shape = [n\_samples, n\_classes]

Returns the probability of the sample for each class in the model, where classes are ordered as they are in `self.classes_`.

**score (X, y, sample\_weight=None)**

Returns the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

**Parameters X** : array-like, shape = (n\_samples, n\_features)

Test samples.

**y** : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True labels for X.

**sample\_weight** : array-like, shape = [n\_samples], optional

Sample weights.

**Returns score** : float

Mean accuracy of self.predict(X) wrt. y.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns self** :

**sparsify**()

Convert coefficient matrix to sparse format.

Converts the `coef_` member to a `scipy.sparse` matrix, which for L1-regularized models can be much more memory- and storage-efficient than the usual `numpy.ndarray` representation.

The `intercept_` member is not converted.

**Returns self** : estimator

## Notes

For non-sparse models, i.e. when there are not many zeros in `coef_`, this may actually *increase* memory usage, so use this method with care. A rule of thumb is that the number of zero elements, which can be computed with `(coef_ == 0).sum()`, must be more than 50% for this to provide significant benefits.

After calling this method, further fitting with the `partial_fit` method (if any) will not work until you call `densify`.

## sklearn.linear\_model.MultiTaskElasticNetCV

```
class sklearn.linear_model.MultiTaskElasticNetCV(l1_ratio=0.5, eps=0.001, n_alphas=100,
                                                alphas=None,          fit_intercept=True,
                                                normalize=False,       max_iter=1000,
                                                tol=0.0001,           cv=None,      copy_X=True,
                                                verbose=0,            n_jobs=1,      random_state=None, selection='cyclic')
```

Multi-task L1/L2 ElasticNet with built-in cross-validation.

The optimization objective for MultiTaskElasticNet is:

$$(1 / (2 * n\_samples)) * ||Y - XW||^Fro\_2 + \alpha * l1\_ratio * ||W||_21 + 0.5 * \alpha * (1 - l1\_ratio) * ||W||\_Fro^2$$

Where:

$$\|W\|_2 = \sqrt{\sum_i (\sum_j w_{ij})^2}$$

i.e. the sum of norm of each row.

Read more in the [User Guide](#).

**Parameters**

**eps** : float, optional  
Length of the path. `eps=1e-3` means that  $\alpha_{\min} / \alpha_{\max} = 1e-3$ .

**alphas** : array-like, optional

List of alphas where to compute the models. If not provided, set automatically.

**n\_alphas** : int, optional

Number of alphas along the regularization path

**l1\_ratio** : float or array of floats

The ElasticNet mixing parameter, with  $0 < l1\_ratio \leq 1$ . For  $l1\_ratio = 1$  the penalty is an L1/L2 penalty. For  $l1\_ratio = 0$  it is an L2 penalty. For  $0 < l1\_ratio < 1$ , the penalty is a combination of L1/L2 and L2. This parameter can be a list, in which case the different values are tested by cross-validation and the one giving the best prediction score is used. Note that a good choice of list of values for `l1_ratio` is often to put more values close to 1 (i.e. Lasso) and less close to 0 (i.e. Ridge), as in `[.1, .5, .7, .9, .95, .99, 1]`

**fit\_intercept** : boolean

whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

**normalize** : boolean, optional, default False

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use [`sklearn.preprocessing.StandardScaler`](#) before calling `fit` on an estimator with `normalize=False`.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**max\_iter** : int, optional

The maximum number of iterations

**tol** : float, optional

The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 3-fold cross-validation,
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/None inputs, `KFold` is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**verbose** : bool or integer

Amount of verbosity.

**n\_jobs** : integer, optional

Number of CPUs to use during the cross validation. If `-1`, use all the CPUs. Note that this is used only if multiple values for `l1_ratio` are given.

**selection** : str, default ‘cyclic’

If set to ‘random’, a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to ‘random’) often leads to significantly faster convergence especially when `tol` is higher than `1e-4`.

**random\_state** : int, RandomState instance or None, optional, default None

The seed of the pseudo random number generator that selects a random feature to update. If int, `random_state` is the seed used by the random number generator; If `RandomState` instance, `random_state` is the random number generator; If None, the random number generator is the `RandomState` instance used by `np.random`. Used when `selection == 'random'`.

**Attributes** `intercept_` : array, shape (n\_tasks,)

Independent term in decision function.

`coef_` : array, shape (n\_tasks, n\_features)

Parameter vector ( $W$  in the cost function formula). Note that `coef_` stores the transpose of  $W$ ,  $W^T$ .

`alpha_` : float

The amount of penalization chosen by cross validation

`mse_path_` : array, shape (n\_alphas, n\_folds) or (n\_l1\_ratio, n\_alphas, n\_folds)

mean square error for the test set on each fold, varying alpha

`alphas_` : numpy array, shape (n\_alphas,) or (n\_l1\_ratio, n\_alphas)

The grid of alphas used for fitting, for each `l1_ratio`

`l1_ratio_` : float

best `l1_ratio` obtained by cross-validation.

`n_iter_` : int

number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

## See also:

[`MultiTaskElasticNet`](#), [`ElasticNetCV`](#), [`MultiTaskLassoCV`](#)

## Notes

The algorithm used to fit the model is coordinate descent.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

## Examples

```
>>> from sklearn import linear_model
>>> clf = linear_model.MultiTaskElasticNetCV()
>>> clf.fit([[0,0], [1, 1], [2, 2]],
...          [[0, 0], [1, 1], [2, 2]])
...
MultiTaskElasticNetCV(alphas=None, copy_X=True, cv=None, eps=0.001,
                      fit_intercept=True, l1_ratio=0.5, max_iter=1000, n_alphas=100,
                      n_jobs=1, normalize=False, random_state=None, selection='cyclic',
                      tol=0.0001, verbose=0)
>>> print(clf.coef_)
[[ 0.52875032  0.46958558]
 [ 0.52875032  0.46958558]]
>>> print(clf.intercept_)
[ 0.00166409  0.00166409]
```

## Methods

<code>fit(X, y)</code>	Fit linear model with coordinate descent
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>path(X, y[, l1_ratio, eps, n_alphas, ...])</code>	Compute elastic net path with coordinate descent
<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

`__init__(l1_ratio=0.5, eps=0.001, n_alphas=100, alphas=None, fit_intercept=True, normalize=False, max_iter=1000, tol=0.0001, cv=None, copy_X=True, verbose=0, n_jobs=1, random_state=None, selection='cyclic')`

`fit(X, y)`

Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

**Parameters** `X` : {array-like}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If `y` is mono-output, `X` can be sparse.

`y` : array-like, shape (n\_samples,) or (n\_samples, n\_targets)

Target values

`get_params(deep=True)`

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns params** : mapping of string to any

Parameter names mapped to their values.

```
static path(X, y, l1_ratio=0.5, eps=0.001, n_alphas=100, alphas=None, precompute='auto',
           Xy=None, copy_X=True, coef_init=None, verbose=False, return_n_iter=False, positive=False,
           check_input=True, **params)
Compute elastic net path with coordinate descent
```

The elastic net optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
1 / (2 * n_samples) * ||y - Xw||^2_2
+ alpha * l1_ratio * ||w||_1
+ 0.5 * alpha * (1 - l1_ratio) * ||w||^2_2
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^Fro_2
+ alpha * l1_ratio * ||W||_21
+ 0.5 * alpha * (1 - l1_ratio) * ||W||_Fro^2
```

Where:

```
||W||_21 = \sum_i \sqrt{\sum_j w_{ij}^2}
```

i.e. the sum of norm of each row.

Read more in the [User Guide](#).

**Parameters** **X** : {array-like}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If **y** is mono-output then **X** can be sparse.

**y** : ndarray, shape (n\_samples,) or (n\_samples, n\_outputs)

Target values

**l1\_ratio** : float, optional

float between 0 and 1 passed to elastic net (scaling between 11 and 12 penalties).  
l1\_ratio=1 corresponds to the Lasso

**eps** : float

Length of the path. **eps**=1e-3 means that **alpha\_min** / **alpha\_max** = 1e-3

**n\_alphas** : int, optional

Number of alphas along the regularization path

**alphas** : ndarray, optional

List of alphas where to compute the models. If None alphas are set automatically

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**Xy** : array-like, optional

**Xy** = np.dot(**X**.T, **y**) that can be precomputed. It is useful only when the Gram matrix is precomputed.

**copy\_X** : boolean, optional, default True  
 If `True`,  $X$  will be copied; else, it may be overwritten.

**coef\_init** : array, shape ( $n\_features$ , ) | None  
 The initial values of the coefficients.

**verbose** : bool or integer  
 Amount of verbosity.

**params** : kwargs  
 keyword arguments passed to the coordinate descent solver.

**return\_n\_iter** : bool  
 whether to return the number of iterations or not.

**positive** : bool, default False  
 If set to `True`, forces coefficients to be positive. (Only allowed when `y.ndim == 1`).

**check\_input** : bool, default `True`  
 Skip input validation checks, including the Gram matrix when provided assuming there are handled by the caller when `check_input=False`.

**Returns** `alphas` : array, shape ( $n\_alphas$ ,)  
 The alphas along the path where models are computed.

`coefs` : array, shape ( $n\_features$ ,  $n\_alphas$ ) or ( $n\_outputs$ ,  $n\_features$ ,  $n\_alphas$ )  
 Coefficients along the path.

`dual_gaps` : array, shape ( $n\_alphas$ ,)  
 The dual gaps at the end of the optimization for each alpha.

`n_iters` : array-like, shape ( $n\_alphas$ ,)  
 The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha. (Is returned when `return_n_iter` is set to `True`).

**See also:**

[MultiTaskElasticNet](#), [MultiTaskElasticNetCV](#), [ElasticNet](#), [ElasticNetCV](#)

**Notes**

See examples/linear\_model/plot\_lasso\_coordinate\_descent\_path.py for an example.

**predict** ( $X$ )

Predict using the linear model

**Parameters** `X` : {array-like, sparse matrix}, shape = ( $n\_samples$ ,  $n\_features$ )

Samples.

**Returns** `C` : array, shape = ( $n\_samples$ ,)

Returns predicted values.

**score**(X, y, sample\_weight=None)

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - \frac{u}{v})$ , where u is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and v is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

**Parameters** X : array-like, shape = (n\_samples, n\_features)

Test samples.

y : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for X.

sample\_weight : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** score : float

R^2 of self.predict(X) wrt. y.

**set\_params**(\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** self :

**sklearn.linear\_model.MultiTaskLassoCV**

```
class sklearn.linear_model.MultiTaskLassoCV(eps=0.001, n_alphas=100, alphas=None,
                                             fit_intercept=True, normalize=False,
                                             max_iter=1000, tol=0.0001, copy_X=True,
                                             cv=None, verbose=False, n_jobs=1, random_state=None, selection='cyclic')
```

Multi-task L1/L2 Lasso with built-in cross-validation.

The optimization objective for MultiTaskLasso is:

$$\frac{1}{2} \cdot (\|W\|_F^2 + \alpha \|W\|_1)$$

Where:

$$\|W\|_1 = \sum_i \sqrt{\sum_j w_{ij}^2}$$

i.e. the sum of norm of each row.

Read more in the [User Guide](#).

**Parameters** eps : float, optional

Length of the path. eps=1e-3 means that alpha\_min / alpha\_max = 1e-3.

alphas : array-like, optional

List of alphas where to compute the models. If not provided, set automatically.

n\_alphas : int, optional

Number of alphas along the regularization path

**fit\_intercept** : boolean

whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

**normalize** : boolean, optional, default False

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use `sklearn.preprocessing.StandardScaler` before calling `fit` on an estimator with `normalize=False`.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**max\_iter** : int, optional

The maximum number of iterations.

**tol** : float, optional

The tolerance for the optimization: if the updates are smaller than `tol`, the optimization code checks the dual gap for optimality and continues until it is smaller than `tol`.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 3-fold cross-validation,
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/None inputs, `KFold` is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**verbose** : bool or integer

Amount of verbosity.

**n\_jobs** : integer, optional

Number of CPUs to use during the cross validation. If -1, use all the CPUs. Note that this is used only if multiple values for `l1_ratio` are given.

**selection** : str, default ‘cyclic’

If set to ‘random’, a random coefficient is updated every iteration rather than looping over features sequentially by default. This (setting to ‘random’) often leads to significantly faster convergence especially when `tol` is higher than 1e-4.

**random\_state** : int, RandomState instance or None, optional, default None

The seed of the pseudo random number generator that selects a random feature to update. If int, `random_state` is the seed used by the random number generator; If `RandomState` instance, `random_state` is the random number generator; If None, the random number generator is the `RandomState` instance used by `np.random`. Used when `selection == ‘random’`

**Attributes** `intercept_` : array, shape (n\_tasks,)

Independent term in decision function.

**coef\_** : array, shape (n\_tasks, n\_features)

Parameter vector ( $W$  in the cost function formula). Note that `coef_` stores the transpose of  $W$ ,  $W^T$ .

**alpha\_** : float

The amount of penalization chosen by cross validation

**mse\_path\_** : array, shape (n\_alphas, n\_folds)

mean square error for the test set on each fold, varying alpha

**alphas\_** : numpy array, shape (n\_alphas,)

The grid of alphas used for fitting.

**n\_iter\_** : int

number of iterations run by the coordinate descent solver to reach the specified tolerance for the optimal alpha.

#### Notes

The algorithm used to fit the model is coordinate descent.

To avoid unnecessary memory duplication the `X` argument of the `fit` method should be directly passed as a Fortran-contiguous numpy array.

#### Methods

<code>fit(X, y)</code>	Fit linear model with coordinate descent
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>path(X, y[, eps, n_alphas, alphas, ...])</code>	Compute Lasso path with coordinate descent
<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

```
__init__(eps=0.001, n_alphas=100, alphas=None, fit_intercept=True, normalize=False,
        max_iter=1000, tol=0.0001, copy_X=True, cv=None, verbose=False, n_jobs=1, random_state=None, selection='cyclic')
```

**fit** (`X, y`)

Fit linear model with coordinate descent

Fit is on grid of alphas and best alpha estimated by cross-validation.

**Parameters** `X` : {array-like}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If `y` is mono-output, `X` can be sparse.

`y` : array-like, shape (n\_samples,) or (n\_samples, n\_targets)

Target values

**get\_params (deep=True)**

Get parameters for this estimator.

**Parameters deep** : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns params** : mapping of string to any

Parameter names mapped to their values.

**static path** (*X*, *y*, *eps*=0.001, *n\_alphas*=100, *alphas*=None, *precompute*='auto', *Xy*=None, *copy\_X*=True, *coef\_init*=None, *verbose*=False, *return\_n\_iter*=False, *positive*=False, *\*\*params*)

Compute Lasso path with coordinate descent

The Lasso optimization function varies for mono and multi-outputs.

For mono-output tasks it is:

```
(1 / (2 * n_samples)) * ||y - Xw||^2 + alpha * ||w||_1
```

For multi-output tasks it is:

```
(1 / (2 * n_samples)) * ||Y - XW||^2_Fro + alpha * ||W||_21
```

Where:

$$\|W\|_21 = \sum_i \sqrt{\sum_j w_{ij}^2}$$

i.e. the sum of norm of each row.

Read more in the [User Guide](#).

**Parameters X** : {array-like, sparse matrix}, shape (n\_samples, n\_features)

Training data. Pass directly as Fortran-contiguous data to avoid unnecessary memory duplication. If *y* is mono-output then *X* can be sparse.

**y** : ndarray, shape (n\_samples,), or (n\_samples, n\_outputs)

Target values

**eps** : float, optional

Length of the path. *eps*=1e-3 means that  $\alpha_{\min} / \alpha_{\max} = 1e-3$

**n\_alphas** : int, optional

Number of alphas along the regularization path

**alphas** : ndarray, optional

List of alphas where to compute the models. If None alphas are set automatically

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**Xy** : array-like, optional

$Xy = \text{np.dot}(X.T, y)$  that can be precomputed. It is useful only when the Gram matrix is precomputed.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**coef\_init** : array, shape (n\_features,) | None

The initial values of the coefficients.

**verbose** : bool or integer

Amount of verbosity.

**params** : kwargs

keyword arguments passed to the coordinate descent solver.

**positive** : bool, default False

If set to True, forces coefficients to be positive. (Only allowed when  $y.ndim == 1$ ).

**return\_n\_iter** : bool

whether to return the number of iterations or not.

**Returns** **alphas** : array, shape (n\_alphas,)

The alphas along the path where models are computed.

**coefs** : array, shape (n\_features, n\_alphas) or (n\_outputs, n\_features, n\_alphas)

Coefficients along the path.

**dual\_gaps** : array, shape (n\_alphas,)

The dual gaps at the end of the optimization for each alpha.

**n\_iters** : array-like, shape (n\_alphas,)

The number of iterations taken by the coordinate descent optimizer to reach the specified tolerance for each alpha.

#### See also:

[`lars\_path`](#), [`Lasso`](#), [`LassoLars`](#), [`LassoCV`](#), [`LassoLarsCV`](#), [`sklearn.decomposition.sparse\_encode`](#)

#### Notes

See examples/linear\_model/plot\_lasso\_coordinate\_descent\_path.py for an example.

To avoid unnecessary memory duplication the X argument of the fit method should be directly passed as a Fortran-contiguous numpy array.

Note that in certain cases, the Lars solver may be significantly faster to implement this functionality. In particular, linear interpolation can be used to retrieve model coefficients between the values output by `lars_path`

#### Examples

Comparing lasso\_path and lars\_path with interpolation:

```
>>> X = np.array([[1, 2, 3.1], [2.3, 5.4, 4.3]]).T
>>> y = np.array([1, 2, 3.1])
>>> # Use lasso_path to compute a coefficient path
>>> _, coef_path, _ = lasso_path(X, y, alphas=[5., 1., .5])
>>> print(coef_path)
[[ 0.          0.          0.46874778]
 [ 0.2159048   0.4425765   0.23689075]]
```

```
>>> # Now use lars_path and 1D linear interpolation to compute the
>>> # same path
>>> from sklearn.linear_model import lars_path
>>> alphas, active, coef_path_lars = lars_path(X, y, method='lasso')
>>> from scipy import interpolate
>>> coef_path_continuous = interpolate.interp1d(alphas[::-1],
...                                              coef_path_lars[:, ::-1])
>>> print(coef_path_continuous([5., 1., .5]))
[[ 0.          0.          0.46915237]
 [ 0.2159048   0.4425765   0.23668876]]
```

**predict (X)**

Predict using the linear model

**Parameters** **X** : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** **C** : array, shape = (n\_samples,)

Returns predicted values.

**score (X, y, sample\_weight=None)**

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - u/v)$ , where u is the residual sum of squares  $((y_{true} - y_{pred})^2 \cdot \text{sum}()$  and v is the total sum of squares  $((y_{true} - y_{true}.\text{mean()})^2 \cdot \text{sum}()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

**Parameters** **X** : array-like, shape = (n\_samples, n\_features)

Test samples.

**y** : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for X.

**sample\_weight** : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** **score** : float

R^2 of self.predict(X) wrt. y.

**set\_params (\*\*params)**

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** **self** :

**sklearn.linear\_model.OrthogonalMatchingPursuitCV**

```
class sklearn.linear_model.OrthogonalMatchingPursuitCV(copy=True, fit_intercept=True,
                                                       normalize=True,
                                                       max_iter=None, cv=None,
                                                       n_jobs=1, verbose=False)
```

Cross-validated Orthogonal Matching Pursuit model (OMP)

**Parameters** `copy` : bool, optional

Whether the design matrix X must be copied by the algorithm. A false value is only helpful if X is already Fortran-ordered, otherwise a copy is made anyway.

**fit\_intercept** : boolean, optional

whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

**normalize** : boolean, optional, default True

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use [sklearn.preprocessing.StandardScaler](#) before calling `fit` on an estimator with `normalize=False`.

**max\_iter** : integer, optional

Maximum numbers of iterations to perform, therefore maximum features to include. 10% of `n_features` but at least 5 if available.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the default 3-fold cross-validation,
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/None inputs, KFold is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**n\_jobs** : integer, optional

Number of CPUs to use during the cross validation. If -1, use all the CPUs

**verbose** : boolean or integer, optional

Sets the verbosity amount

**Read more in the :ref:`User Guide <omp>`.** :

**Attributes** `intercept_` : float or array, shape (`n_targets`,)

Independent term in decision function.

`coef_` : array, shape (`n_features`,) or (`n_targets`, `n_features`)

Parameter vector (w in the problem formulation).

`n_nonzero_coefs_` : int

Estimated number of non-zero coefficients giving the best mean squared error over the cross-validation folds.

**n\_iter\_** : int or array-like

Number of active features across every target for the model refit with the best hyperparameters got by cross-validating across all folds.

## Methods

<code>fit(X, y)</code>	Fit the model using X, y as training data.
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

**\_\_init\_\_(copy=True, fit\_intercept=True, normalize=True, max\_iter=None, cv=None, n\_jobs=1, verbose=False)**

**fit(X, y)**

Fit the model using X, y as training data.

**Parameters** `X` : array-like, shape [n\_samples, n\_features]

Training data.

`y` : array-like, shape [n\_samples]

Target values.

**Returns** `self` : object

returns an instance of self.

**get\_params(deep=True)**

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** `params` : mapping of string to any

Parameter names mapped to their values.

**predict(X)**

Predict using the linear model

**Parameters** `X` : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** `C` : array, shape = (n\_samples,)

Returns predicted values.

**score**(X, y, sample\_weight=None)

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - \frac{u}{v})$ , where u is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and v is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

**Parameters** X : array-like, shape = (n\_samples, n\_features)

Test samples.

y : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for X.

sample\_weight : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** score : float

R^2 of self.predict(X) wrt. y.

**set\_params**(\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** self :

## Examples using `sklearn.linear_model.OrthogonalMatchingPursuitCV`

- *Orthogonal Matching Pursuit*

## sklearn.linear\_model.RidgeCV

```
class sklearn.linear_model.RidgeCV(alphas=(0.1, 1.0, 10.0), fit_intercept=True, normalize=False, scoring=None, cv=None, gcv_mode=None, store_cv_values=False)
```

Ridge regression with built-in cross-validation.

By default, it performs Generalized Cross-Validation, which is a form of efficient Leave-One-Out cross-validation.

Read more in the *User Guide*.

**Parameters** alphas : numpy array of shape [n\_alphas]

Array of alpha values to try. Regularization strength; must be a positive float. Regularization improves the conditioning of the problem and reduces the variance of the estimates. Larger values specify stronger regularization. Alpha corresponds to C^-1 in other linear models such as LogisticRegression or LinearSVC.

**fit\_intercept** : boolean

Whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

**normalize** : boolean, optional, default False

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors `X` will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use `sklearn.preprocessing.StandardScaler` before calling `fit` on an estimator with `normalize=False`.

**scoring** : string, callable or None, optional, default: None

A string (see model evaluation documentation) or a scorer callable object / function with signature `scorer(estimator, X, y)`.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the efficient Leave-One-Out cross-validation
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

For integer/None inputs, if `y` is binary or multiclass, `sklearn.model_selection.StratifiedKFold` is used, else, `sklearn.model_selection.KFold` is used.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**gcv\_mode** : {None, ‘auto’, ‘svd’, ‘eigen’}, optional

Flag indicating which strategy to use when performing Generalized Cross-Validation. Options are:

```
'auto' : use svd if n_samples > n_features or when X is a sparse
         matrix, otherwise use eigen
'svd' : force computation via singular value decomposition of X
        (does not work for sparse matrices)
'eigen' : force computation via eigendecomposition of X^T X
```

The ‘auto’ mode is the default and is intended to pick the cheaper option of the two depending upon the shape and format of the training data.

**store\_cv\_values** : boolean, default=False

Flag indicating if the cross-validation values corresponding to each alpha should be stored in the `cv_values_` attribute (see below). This flag is only compatible with `cv=None` (i.e. using Generalized Cross-Validation).

**Attributes** `cv_values_` : array, shape = [n\_samples, n\_alphas] or shape = [n\_samples, n\_targets, n\_alphas], optional

Cross-validation values for each alpha (if `store_cv_values=True` and `cv=None`). After `fit()` has been called, this attribute will contain the mean squared errors (by default) or the values of the `{loss,score}_func` function (if provided in the constructor).

**coef\_** : array, shape = [n\_features] or [n\_targets, n\_features]

Weight vector(s).

**intercept\_** : float | array, shape = (n\_targets,)

Independent term in decision function. Set to 0.0 if `fit_intercept = False`.

**alpha\_** : float

Estimated regularization parameter.

<a href="#"><code>predict(X)</code></a>	Predict using the linear model
<a href="#"><code>score(X, y[, sample_weight])</code></a>	Returns the coefficient of determination R^2 of the prediction.
<a href="#"><code>set_params(**params)</code></a>	Set the parameters of this estimator.

[`\_\_init\_\_\(alphas=\(0.1, 1.0, 10.0\), fit\_intercept=True, normalize=False, scoring=None, cv=None, gcv\_mode=None, store\_cv\_values=False\)`](#)

**fit** (*X*, *y*, *sample\_weight*=None)  
Fit Ridge regression model

**Parameters** *X* : array-like, shape = [n\_samples, n\_features]

Training data

*y* : array-like, shape = [n\_samples] or [n\_samples, n\_targets]

Target values

*sample\_weight* : float or array-like of shape [n\_samples]

Sample weight

**Returns** *self* : Returns self.

[`get\_params\(deep=True\)`](#)

Get parameters for this estimator.

**Parameters** *deep* : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** *params* : mapping of string to any

Parameter names mapped to their values.

[`predict\(X\)`](#)

Predict using the linear model

**Parameters** *X* : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** *C* : array, shape = (n\_samples,)

Returns predicted values.

[`score\(X, y, sample\_weight=None\)`](#)

Returns the coefficient of determination R^2 of the prediction.

The coefficient R<sup>2</sup> is defined as  $(1 - u/v)$ , where  $u$  is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and  $v$  is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of  $y$ , disregarding the input features, would get a R<sup>2</sup> score of 0.0.

**Parameters** `X` : array-like, shape = (n\_samples, n\_features)

Test samples.

`y` : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for `X`.

`sample_weight` : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** `score` : float

R<sup>2</sup> of self.predict(`X`) wrt. `y`.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** `self`:

## Examples using `sklearn.linear_model.RidgeCV`

- Face completion with a multi-output estimators

### `sklearn.linear_model.RidgeClassifierCV`

```
class sklearn.linear_model.RidgeClassifierCV(alphas=(0.1, 1.0, 10.0), fit_intercept=True,
                                             normalize=False, scoring=None, cv=None,
                                             class_weight=None)
```

Ridge classifier with built-in cross-validation.

By default, it performs Generalized Cross-Validation, which is a form of efficient Leave-One-Out cross-validation. Currently, only the `n_features > n_samples` case is handled efficiently.

Read more in the [User Guide](#).

**Parameters** `alphas` : numpy array of shape [n\_alphas]

Array of alpha values to try. Regularization strength; must be a positive float. Regularization improves the conditioning of the problem and reduces the variance of the estimates. Larger values specify stronger regularization. Alpha corresponds to C<sup>-1</sup> in other linear models such as LogisticRegression or LinearSVC.

**fit\_intercept** : boolean

Whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

**normalize** : boolean, optional, default False

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use `sklearn.preprocessing.StandardScaler` before calling `fit` on an estimator with `normalize=False`.

**scoring** : string, callable or None, optional, default: None

A string (see model evaluation documentation) or a scorer callable object / function with signature `scorer(estimator, X, y)`.

**cv** : int, cross-validation generator or an iterable, optional

Determines the cross-validation splitting strategy. Possible inputs for cv are:

- None, to use the efficient Leave-One-Out cross-validation
- integer, to specify the number of folds.
- An object to be used as a cross-validation generator.
- An iterable yielding train/test splits.

Refer [User Guide](#) for the various cross-validation strategies that can be used here.

**class\_weight** : dict or ‘balanced’, optional

Weights associated with classes in the form `{class_label: weight}`. If not given, all classes are supposed to have weight one.

The “balanced” mode uses the values of y to automatically adjust weights inversely proportional to class frequencies in the input data as `n_samples / (n_classes * np.bincount(y))`

**Attributes** `cv_values_` : array, shape = [n\_samples, n\_alphas] or shape = [n\_samples, n\_responses, n\_alphas], optional

Cross-validation values for each alpha (if `store_cv_values=True` and

**‘cv=None’). After ‘fit()’ has been called, this attribute will contain the mean squared errors (by default) or the values of the ‘{loss,score}\_func’ function (if provided in the constructor).**

:

`coef_` : array, shape = [n\_features] or [n\_targets, n\_features]

Weight vector(s).

`intercept_` : float | array, shape = (n\_targets,)

Independent term in decision function. Set to 0.0 if `fit_intercept = False`.

`alpha_` : float

Estimated regularization parameter

## Notes

For multi-class classification, n\_class classifiers are trained in a one-versus-all approach. Concretely, this is implemented by taking advantage of the multi-variate response support in Ridge.

## Methods

<code>decision_function(X)</code>	Predict confidence scores for samples.
<code>fit(X, y[, sample_weight])</code>	Fit the ridge classifier.
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict class labels for samples in X.
<code>score(X, y[, sample_weight])</code>	Returns the mean accuracy on the given test data and labels.
<code>set_params(**params)</code>	Set the parameters of this estimator.

`__init__(alphas=(0.1, 1.0, 10.0), fit_intercept=True, normalize=False, scoring=None, cv=None, class_weight=None)`

**decision\_function(X)**

Predict confidence scores for samples.

The confidence score for a sample is the signed distance of that sample to the hyperplane.

**Parameters** `X` : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** array, shape=(n\_samples,) if n\_classes == 2 else (n\_samples, n\_classes) :

Confidence scores per (sample, class) combination. In the binary case, confidence score for self.classes\_[1] where >0 means this class would be predicted.

`fit(X, y, sample_weight=None)`

Fit the ridge classifier.

**Parameters** `X` : array-like, shape (n\_samples, n\_features)

Training vectors, where n\_samples is the number of samples and n\_features is the number of features.

`y` : array-like, shape (n\_samples,)

Target values.

`sample_weight` : float or numpy array of shape (n\_samples,)

Sample weight.

**Returns** `self` : object

Returns self.

`get_params(deep=True)`

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** `params` : mapping of string to any

Parameter names mapped to their values.

**`predict` (*X*)**

Predict class labels for samples in *X*.

**Parameters** *X* : {array-like, sparse matrix}, shape = [n\_samples, n\_features]

Samples.

**Returns** *C* : array, shape = [n\_samples]

Predicted class label per sample.

**`score` (*X*, *y*, *sample\_weight=None*)**

Returns the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

**Parameters** *X* : array-like, shape = (n\_samples, n\_features)

Test samples.

*y* : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True labels for *X*.

**sample\_weight** : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** *score* : float

Mean accuracy of self.predict(*X*) wrt. *y*.

**`set_params` (\*\**params*)**

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** *self* :

## Information Criterion

Some models can offer an information-theoretic closed-form formula of the optimal estimate of the regularization parameter by computing a single regularization path (instead of several when using cross-validation).

Here is the list of models benefitting from the Akaike Information Criterion (AIC) or the Bayesian Information Criterion (BIC) for automated model selection:

---

`linear_model.LassoLarsIC`([criterion, ...])

Lasso model fit with Lars using BIC or AIC for model selection

---

**sklearn.linear\_model.LassoLarsIC**

```
class sklearn.linear_model.LassoLarsIC(criterion='aic', fit_intercept=True, verbose=False,
                                         normalize=True, precompute='auto', max_iter=500,
                                         eps=2.2204460492503131e-16, copy_X=True, positive=False)
```

Lasso model fit with Lars using BIC or AIC for model selection

The optimization objective for Lasso is:

$$(1 / (2 * n\_samples)) * ||y - Xw||^2_2 + \alpha * ||w||_1$$

AIC is the Akaike information criterion and BIC is the Bayes Information criterion. Such criteria are useful to select the value of the regularization parameter by making a trade-off between the goodness of fit and the complexity of the model. A good model should explain well the data while being simple.

Read more in the [User Guide](#).

**Parameters** `criterion` : ‘bic’ | ‘aic’

The type of criterion to use.

**fit\_intercept** : boolean

whether to calculate the intercept for this model. If set to false, no intercept will be used in calculations (e.g. data is expected to be already centered).

**positive** : boolean (default=False)

Restrict coefficients to be  $\geq 0$ . Be aware that you might want to remove `fit_intercept` which is set True by default. Under the positive restriction the model coefficients do not converge to the ordinary-least-squares solution for small values of alpha. Only coefficients up to the smallest alpha value (`alphas_[alphas_ > 0.].min()` when `fit_path=True`) reached by the stepwise Lars-Lasso algorithm are typically in congruence with the solution of the coordinate descent Lasso estimator. As a consequence using `LassoLarsIC` only makes sense for problems where a sparse solution is expected and/or reached.

**verbose** : boolean or integer, optional

Sets the verbosity amount

**normalize** : boolean, optional, default True

This parameter is ignored when `fit_intercept` is set to False. If True, the regressors X will be normalized before regression by subtracting the mean and dividing by the l2-norm. If you wish to standardize, please use [`sklearn.preprocessing.StandardScaler`](#) before calling `fit` on an estimator with `normalize=False`.

**copy\_X** : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**precompute** : True | False | ‘auto’ | array-like

Whether to use a precomputed Gram matrix to speed up calculations. If set to ‘auto’ let us decide. The Gram matrix can also be passed as argument.

**max\_iter** : integer, optional

Maximum number of iterations to perform. Can be used for early stopping.

**eps** : float, optional

The machine-precision regularization in the computation of the Cholesky diagonal factors. Increase this for very ill-conditioned systems. Unlike the `tol` parameter in some iterative optimization-based algorithms, this parameter does not control the tolerance of the optimization.

**Attributes**

- `coef_`** : array, shape (n\_features,)  
parameter vector ( $w$  in the formulation formula)
- `intercept_`** : float  
independent term in decision function.
- `alpha_`** : float  
the alpha parameter chosen by the information criterion
- `n_iter_`** : int  
number of iterations run by `lars_path` to find the grid of alphas.
- `criterion_`** : array, shape (n\_alphas,)  
The value of the information criteria ('aic', 'bic') across all alphas. The alpha which has the smallest information criteria is chosen.

#### Notes

The estimation of the number of degrees of freedom is given by:

“On the degrees of freedom of the lasso” Hui Zou, Trevor Hastie, and Robert Tibshirani Ann. Statist. Volume 35, Number 5 (2007), 2173-2192.

[https://en.wikipedia.org/wiki/Akaike\\_information\\_criterion](https://en.wikipedia.org/wiki/Akaike_information_criterion)

[https://en.wikipedia.org/wiki/Bayesian\\_information\\_criterion](https://en.wikipedia.org/wiki/Bayesian_information_criterion)

#### Examples

```
>>> from sklearn import linear_model
>>> clf = linear_model.LassoLarsIC(criterion='bic')
>>> clf.fit([[1, 1], [0, 0], [1, 1], [-1.1111, 0, -1.1111]])
...
LassoLarsIC(copy_X=True, criterion='bic', eps=..., fit_intercept=True,
            max_iter=500, normalize=True, positive=False, precompute='auto',
            verbose=False)
>>> print(clf.coef_)
[ 0. -1.11...]
```

#### Methods

---

`fit(X, y[, copy_X])` Fit the model using  $X$ ,  $y$  as training data.

`get_params([deep])` Get parameters for this estimator.

Continued on next page

Table 3.14 – continued from previous page

<code>predict(X)</code>	Predict using the linear model
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.

`__init__(criterion='aic', fit_intercept=True, verbose=False, normalize=True, precompute='auto', max_iter=500, eps=2.2204460492503131e-16, copy_X=True, positive=False)`

`fit(X, y, copy_X=True)`

Fit the model using X, y as training data.

**Parameters** `X` : array-like, shape (n\_samples, n\_features)

training data.

`y` : array-like, shape (n\_samples,)

target values.

`copy_X` : boolean, optional, default True

If True, X will be copied; else, it may be overwritten.

**Returns** `self` : object

returns an instance of self.

`get_params(deep=True)`

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** `params` : mapping of string to any

Parameter names mapped to their values.

`predict(X)`

Predict using the linear model

**Parameters** `X` : {array-like, sparse matrix}, shape = (n\_samples, n\_features)

Samples.

**Returns** `C` : array, shape = (n\_samples,)

Returns predicted values.

`score(X, y, sample_weight=None)`

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - u/v)$ , where u is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and v is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R^2 score of 0.0.

**Parameters** `X` : array-like, shape = (n\_samples, n\_features)

Test samples.

`y` : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for X.

**sample\_weight** : array-like, shape = [n\_samples], optional

Sample weights.

**Returns score** : float

R^2 of self.predict(X) wrt. y.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns self** :

## Examples using `sklearn.linear_model.LassoLarsIC`

- *Lasso model selection: Cross-Validation / AIC / BIC*

## Out of Bag Estimates

When using ensemble methods base upon bagging, i.e. generating new training sets using sampling with replacement, part of the training set remains unused. For each classifier in the ensemble, a different part of the training set is left out.

This left out portion can be used to estimate the generalization error without having to rely on a separate validation set. This estimate comes “for free” as no additional data is needed and can be used for model selection.

This is currently implemented in the following classes:

<code>ensemble.RandomForestClassifier(...)</code>	A random forest classifier.
<code>ensemble.RandomForestRegressor(...)</code>	A random forest regressor.

**sklearn.ensemble.RandomForestClassifier**

```
class sklearn.ensemble.RandomForestClassifier(n_estimators=10, criterion='gini', max_depth=None, min_samples_split=2, min_samples_leaf=1, min_weight_fraction_leaf=0.0, max_features='auto', max_leaf_nodes=None, min_impurity_decrease=0.0, min_impurity_split=None, bootstrap=True, oob_score=False, n_jobs=1, random_state=None, verbose=0, warm_start=False, class_weight=None)
```

A random forest classifier.

A random forest is a meta estimator that fits a number of decision tree classifiers on various sub-samples of the dataset and use averaging to improve the predictive accuracy and control over-fitting. The sub-sample size is always the same as the original input sample size but the samples are drawn with replacement if `bootstrap=True` (default).

Read more in the [User Guide](#).

**Parameters** `n_estimators` : integer, optional (default=10)

The number of trees in the forest.

`criterion` : string, optional (default="gini")

The function to measure the quality of a split. Supported criteria are “gini” for the Gini impurity and “entropy” for the information gain. Note: this parameter is tree-specific.

`max_features` : int, float, string or None, optional (default="auto")

The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.
- If float, then `max_features` is a percentage and `int(max_features * n_features)` features are considered at each split.
- If “auto”, then `max_features=sqrt(n_features)`.
- If “sqrt”, then `max_features=sqrt(n_features)` (same as “auto”).
- If “log2”, then `max_features=log2(n_features)`.
- If None, then `max_features=n_features`.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

`max_depth` : integer or None, optional (default=None)

The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than `min_samples_split` samples.

`min_samples_split` : int, float, optional (default=2)

The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.

- If float, then `min_samples_split` is a percentage and  $\text{ceil}(\text{min\_samples\_split} * n_{\text{samples}})$  are the minimum number of samples for each split.

Changed in version 0.18: Added float values for percentages.

**min\_samples\_leaf** : int, float, optional (default=1)

The minimum number of samples required to be at a leaf node:

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a percentage and  $\text{ceil}(\text{min\_samples\_leaf} * n_{\text{samples}})$  are the minimum number of samples for each node.

Changed in version 0.18: Added float values for percentages.

**min\_weight\_fraction\_leaf** : float, optional (default=0.)

The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when `sample_weight` is not provided.

**max\_leaf\_nodes** : int or None, optional (default=None)

Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

**min\_impurity\_split** : float,

Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19 and will be removed in 0.21. Use `min_impurity_decrease` instead.

**min\_impurity\_decrease** : float, optional (default=0.)

A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

$$\frac{N_t}{N} \cdot (\text{impurity} - \frac{N_{t,R}}{N_t} \cdot \text{right\_impurity} - \frac{N_{t,L}}{N_t} \cdot \text{left\_impurity})$$

where  $N$  is the total number of samples,  $N_t$  is the number of samples at the current node,  $N_{t,L}$  is the number of samples in the left child, and  $N_{t,R}$  is the number of samples in the right child.

$N$ ,  $N_t$ ,  $N_{t,R}$  and  $N_{t,L}$  all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

**bootstrap** : boolean, optional (default=True)

Whether bootstrap samples are used when building trees.

**oob\_score** : bool (default=False)

Whether to use out-of-bag samples to estimate the generalization accuracy.

**n\_jobs** : integer, optional (default=1)

The number of jobs to run in parallel for both *fit* and *predict*. If -1, then the number of jobs is set to the number of cores.

**random\_state** : int, RandomState instance or None, optional (default=None)

If int, `random_state` is the seed used by the random number generator; If RandomState instance, `random_state` is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`.

**verbose** : int, optional (default=0)

Controls the verbosity of the tree building process.

**warm\_start** : bool, optional (default=False)

When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest.

**class\_weight** : dict, list of dicts, “balanced”,

“balanced\_subsample” or None, optional (default=None) Weights associated with classes in the form {class\_label: weight}. If not given, all classes are supposed to have weight one. For multi-output problems, a list of dicts can be provided in the same order as the columns of `y`.

Note that for multioutput (including multilabel) weights should be defined for each class of every column in its own dict. For example, for four-class multilabel classification weights should be [{0: 1, 1: 1}, {0: 1, 1: 5}, {0: 1, 1: 1}, {0: 1, 1: 1}] instead of [{1:1}, {2:5}, {3:1}, {4:1}].

The “balanced” mode uses the values of `y` to automatically adjust weights inversely proportional to class frequencies in the input data as `n_samples / (n_classes * np.bincount(y))`

The “balanced\_subsample” mode is the same as “balanced” except that weights are computed based on the bootstrap sample for every tree grown.

For multi-output, the weights of each column of `y` will be multiplied.

Note that these weights will be multiplied with `sample_weight` (passed through the `fit` method) if `sample_weight` is specified.

**Attributes** `estimators_` : list of DecisionTreeClassifier

The collection of fitted sub-estimators.

`classes_` : array of shape = [n\_classes] or a list of such arrays

The classes labels (single output problem), or a list of arrays of class labels (multi-output problem).

`n_classes_` : int or list

The number of classes (single output problem), or a list containing the number of classes for each output (multi-output problem).

`n_features_` : int

The number of features when `fit` is performed.

`n_outputs_` : int

The number of outputs when `fit` is performed.

`feature_importances_` : array of shape = [n\_features]

The feature importances (the higher, the more important the feature).

**oob\_score\_** : float

Score of the training dataset obtained using an out-of-bag estimate.

**oob\_decision\_function\_** : array of shape = [n\_samples, n\_classes]

Decision function computed with out-of-bag estimate on the training set. If n\_estimators is small it might be possible that a data point was never left out during the bootstrap. In this case, *oob\_decision\_function\_* might contain NaN.

`DecisionTreeClassifier`, `ExtraTreesClassifier`

### Notes

The default values for the parameters controlling the size of the trees (e.g. `max_depth`, `min_samples_leaf`, etc.) lead to fully grown and unpruned trees which can potentially be very large on some data sets. To reduce memory consumption, the complexity and size of the trees should be controlled by setting those parameter values.

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data, `max_features=n_features` and `bootstrap=False`, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, `random_state` has to be fixed.

### Methods

<code>apply(X)</code>	Apply trees in the forest to X, return leaf indices.
<code>decision_path(X)</code>	Return the decision path in the forest
<code>fit(X, y[, sample_weight])</code>	Build a forest of trees from the training set (X, y).
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict class for X.
<code>predict_log_proba(X)</code>	Predict class log-probabilities for X.
<code>predict_proba(X)</code>	Predict class probabilities for X.
<code>score(X, y[, sample_weight])</code>	Returns the mean accuracy on the given test data and labels.
<code>set_params(**params)</code>	Set the parameters of this estimator.

```
__init__(n_estimators=10,      criterion='gini',      max_depth=None,      min_samples_split=2,
        min_samples_leaf=1,      min_weight_fraction_leaf=0.0,      max_features='auto',
        max_leaf_nodes=None,      min_impurity_decrease=0.0,      min_impurity_split=None,
        bootstrap=True,      oob_score=False,      n_jobs=1,      random_state=None,      verbose=0,
        warm_start=False,      class_weight=None)
```

**apply (X)**

Apply trees in the forest to X, return leaf indices.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `X_leaves` : array-like, shape = [n\_samples, n\_estimators]

For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

**decision\_path**(`X`)

Return the decision path in the forest

New in version 0.18.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `indicator` : sparse csr array, shape = [n\_samples, n\_nodes]

Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

`n_nodes_ptr` : array of size (n\_estimators + 1, )

The columns from `indicator[n_nodes_ptr[i]:n_nodes_ptr[i+1]]` gives the indicator value for the i-th estimator.

**feature\_importances\_**

Return the feature importances (the higher, the more important the feature).

**Returns** `feature_importances_` : array, shape = [n\_features]

**fit**(`X, y, sample_weight=None`)

Build a forest of trees from the training set (`X, y`).

**Parameters** `X` : array-like or sparse matrix of shape = [n\_samples, n\_features]

The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

`y` : array-like, shape = [n\_samples] or [n\_samples, n\_outputs]

The target values (class labels in classification, real numbers in regression).

`sample_weight` : array-like, shape = [n\_samples] or None

Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

**Returns** `self` : object

Returns self.

**get\_params**(`deep=True`)

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns params** : mapping of string to any

Parameter names mapped to their values.

**predict** (*X*)

Predict class for *X*.

The predicted class of an input sample is a vote by the trees in the forest, weighted by their probability estimates. That is, the predicted class is the one with highest mean probability estimate across the trees.

**Parameters X** : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns y** : array of shape = [n\_samples] or [n\_samples, n\_outputs]

The predicted classes.

**predict\_log\_proba** (*X*)

Predict class log-probabilities for *X*.

The predicted class log-probabilities of an input sample is computed as the log of the mean predicted class probabilities of the trees in the forest.

**Parameters X** : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns p** : array of shape = [n\_samples, n\_classes], or a list of n\_outputs

such arrays if `n_outputs > 1`. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute `classes_`.

**predict\_proba** (*X*)

Predict class probabilities for *X*.

The predicted class probabilities of an input sample are computed as the mean predicted class probabilities of the trees in the forest. The class probability of a single tree is the fraction of samples of the same class in a leaf.

**Parameters X** : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns p** : array of shape = [n\_samples, n\_classes], or a list of n\_outputs

such arrays if `n_outputs > 1`. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute `classes_`.

**score** (*X*, *y*, *sample\_weight=None*)

Returns the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

**Parameters X** : array-like, shape = (n\_samples, n\_features)

Test samples.

**y** : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True labels for X.

**sample\_weight** : array-like, shape = [n\_samples], optional

Sample weights.

**Returns score** : float

Mean accuracy of self.predict(X) wrt. y.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns self** :

## sklearn.ensemble.RandomForestRegressor

```
class sklearn.ensemble.RandomForestRegressor(n_estimators=10,          criti-
                                              rion='mse',           max_depth=None,
                                              min_samples_split=2,   min_samples_leaf=1,
                                              min_weight_fraction_leaf=0.0,
                                              max_features='auto',  max_leaf_nodes=None,
                                              min_impurity_decrease=0.0,
                                              min_impurity_split=None,   boot-
                                              strap=True,    oob_score=False,   n_jobs=1,
                                              random_state=None,      verbose=0,
                                              warm_start=False)
```

A random forest regressor.

A random forest is a meta estimator that fits a number of classifying decision trees on various sub-samples of the dataset and use averaging to improve the predictive accuracy and control over-fitting. The sub-sample size is always the same as the original input sample size but the samples are drawn with replacement if `bootstrap=True` (default).

Read more in the [User Guide](#).

**Parameters** `n_estimators` : integer, optional (default=10)

The number of trees in the forest.

**criterion** : string, optional (default="mse")

The function to measure the quality of a split. Supported criteria are “mse” for the mean squared error, which is equal to variance reduction as feature selection criterion, and “mae” for the mean absolute error.

New in version 0.18: Mean Absolute Error (MAE) criterion.

**max\_features** : int, float, string or None, optional (default="auto")

The number of features to consider when looking for the best split:

- If int, then consider  $\text{max\_features}$  features at each split.
- If float, then  $\text{max\_features}$  is a percentage and  $\text{int}(\text{max\_features} * n\_features)$  features are considered at each split.
- If “auto”, then  $\text{max\_features}=n\_features$ .
- If “sqrt”, then  $\text{max\_features}=\sqrt{n\_features}$ .
- If “log2”, then  $\text{max\_features}=\log_2(n\_features)$ .
- If None, then  $\text{max\_features}=n\_features$ .

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than  $\text{max\_features}$  features.

**max\_depth** : integer or None, optional (default=None)

The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than  $\text{min\_samples\_split}$  samples.

**min\_samples\_split** : int, float, optional (default=2)

The minimum number of samples required to split an internal node:

- If int, then consider  $\text{min\_samples\_split}$  as the minimum number.
- If float, then  $\text{min\_samples\_split}$  is a percentage and  $\text{ceil}(\text{min\_samples\_split} * n\_samples)$  are the minimum number of samples for each split.

Changed in version 0.18: Added float values for percentages.

**min\_samples\_leaf** : int, float, optional (default=1)

The minimum number of samples required to be at a leaf node:

- If int, then consider  $\text{min\_samples\_leaf}$  as the minimum number.
- If float, then  $\text{min\_samples\_leaf}$  is a percentage and  $\text{ceil}(\text{min\_samples\_leaf} * n\_samples)$  are the minimum number of samples for each node.

Changed in version 0.18: Added float values for percentages.

**min\_weight\_fraction\_leaf** : float, optional (default=0.)

The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when  $\text{sample\_weight}$  is not provided.

**max\_leaf\_nodes** : int or None, optional (default=None)

Grow trees with  $\text{max\_leaf\_nodes}$  in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

**min\_impurity\_split** : float,

Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19 and will be removed in 0.21. Use `min_impurity_decrease` instead.

**min\_impurity\_decrease** : float, optional (default=0.)

A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

$$\frac{N_t}{N} * (\text{impurity} - \frac{N_{t\_R}}{N_t} * \text{right\_impurity} - \frac{N_{t\_L}}{N_t} * \text{left\_impurity})$$

where  $N$  is the total number of samples,  $N_t$  is the number of samples at the current node,  $N_{t\_L}$  is the number of samples in the left child, and  $N_{t\_R}$  is the number of samples in the right child.

$N$ ,  $N_t$ ,  $N_{t\_R}$  and  $N_{t\_L}$  all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

**bootstrap** : boolean, optional (default=True)

Whether bootstrap samples are used when building trees.

**oob\_score** : bool, optional (default=False)

whether to use out-of-bag samples to estimate the  $R^2$  on unseen data.

**n\_jobs** : integer, optional (default=1)

The number of jobs to run in parallel for both `fit` and `predict`. If -1, then the number of jobs is set to the number of cores.

**random\_state** : int, RandomState instance or None, optional (default=None)

If int, `random_state` is the seed used by the random number generator; If RandomState instance, `random_state` is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`.

**verbose** : int, optional (default=0)

Controls the verbosity of the tree building process.

**warm\_start** : bool, optional (default=False)

When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest.

**Attributes** **estimators\_** : list of DecisionTreeRegressor

The collection of fitted sub-estimators.

**feature\_importances\_** : array of shape = [n\_features]

The feature importances (the higher, the more important the feature).

**n\_features\_** : int

The number of features when `fit` is performed.

**n\_outputs\_** : intThe number of outputs when `fit` is performed.**oob\_score\_** : float

Score of the training dataset obtained using an out-of-bag estimate.

**oob\_prediction\_** : array of shape = [n\_samples]

Prediction computed with out-of-bag estimate on the training set.

**See also:**`DecisionTreeRegressor`, `ExtraTreesRegressor`**Notes**

The default values for the parameters controlling the size of the trees (e.g. `max_depth`, `min_samples_leaf`, etc.) lead to fully grown and unpruned trees which can potentially be very large on some data sets. To reduce memory consumption, the complexity and size of the trees should be controlled by setting those parameter values.

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data, `max_features=n_features` and `bootstrap=False`, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, `random_state` has to be fixed.

```

**apply (X)**

Apply trees in the forest to X, return leaf indices.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If

a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns `X_leaves`** : array\_like, shape = [n\_samples, n\_estimators]

For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

**`decision_path(X)`**

Return the decision path in the forest

New in version 0.18.

**Parameters `X`** : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns `indicator`** : sparse csr array, shape = [n\_samples, n\_nodes]

Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

**`n_nodes_ptr`** : array of size (n\_estimators + 1, )

The columns from `indicator[n_nodes_ptr[i]:n_nodes_ptr[i+1]]` gives the indicator value for the i-th estimator.

**`feature_importances_`**

Return the feature importances (the higher, the more important the feature).

**Returns `feature_importances_`** : array, shape = [n\_features]

**`fit(X, y, sample_weight=None)`**

Build a forest of trees from the training set (X, y).

**Parameters `X`** : array-like or sparse matrix of shape = [n\_samples, n\_features]

The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

**`y`** : array-like, shape = [n\_samples] or [n\_samples, n\_outputs]

The target values (class labels in classification, real numbers in regression).

**`sample_weight`** : array-like, shape = [n\_samples] or None

Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

**Returns `self`** : object

Returns self.

**`get_params(deep=True)`**

Get parameters for this estimator.

**Parameters `deep`** : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns `params`** : mapping of string to any

Parameter names mapped to their values.

**predict**(*X*)

Predict regression target for *X*.

The predicted regression target of an input sample is computed as the mean predicted regression targets of the trees in the forest.

**Parameters** *X* : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** *y* : array of shape = [n\_samples] or [n\_samples, n\_outputs]

The predicted values.

**score**(*X*, *y*, *sample\_weight=None*)

Returns the coefficient of determination R^2 of the prediction.

The coefficient R^2 is defined as  $(1 - u/v)$ , where *u* is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and *v* is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of *y*, disregarding the input features, would get a R^2 score of 0.0.

**Parameters** *X* : array-like, shape = (n\_samples, n\_features)

Test samples.

*y* : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for *X*.

*sample\_weight* : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** *score* : float

R^2 of self.predict(*X*) wrt. *y*.

**set\_params**(\**params*)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

**Returns** *self* :

## Examples using `sklearn.ensemble.RandomForestRegressor`

- *Imputing missing values before building an estimator*
- *Prediction Latency*
- *Comparing random forests and the multi-output meta estimator*

**sklearn.ensemble.ExtraTreesClassifier**

```
class sklearn.ensemble.ExtraTreesClassifier(n_estimators=10,
                                             criterion='gini',
                                             max_depth=None,
                                             min_samples_split=2,
                                             min_samples_leaf=1,
                                             min_weight_fraction_leaf=0.0,
                                             max_features='auto',
                                             max_leaf_nodes=None,
                                             min_impurity_decrease=0.0,
                                             min_impurity_split=None,
                                             bootstrap=False,
                                             oob_score=False,
                                             n_jobs=1,
                                             random_state=None,
                                             verbose=0,
                                             warm_start=False,
                                             class_weight=None)
```

An extra-trees classifier.

This class implements a meta estimator that fits a number of randomized decision trees (a.k.a. extra-trees) on various sub-samples of the dataset and use averaging to improve the predictive accuracy and control over-fitting.

Read more in the [User Guide](#).

**Parameters** **n\_estimators** : integer, optional (default=10)

The number of trees in the forest.

**criterion** : string, optional (default="gini")

The function to measure the quality of a split. Supported criteria are “gini” for the Gini impurity and “entropy” for the information gain.

**max\_features** : int, float, string or None, optional (default="auto")

The number of features to consider when looking for the best split:

- If int, then consider *max\_features* features at each split.
- If float, then *max\_features* is a percentage and  $\text{int}(\text{max\_features} * \text{n\_features})$  features are considered at each split.
- If “auto”, then  $\text{max\_features} = \sqrt{\text{n\_features}}$ .
- If “sqrt”, then  $\text{max\_features} = \sqrt{\text{n\_features}}$ .
- If “log2”, then  $\text{max\_features} = \log_2(\text{n\_features})$ .
- If None, then  $\text{max\_features} = \text{n\_features}$ .

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than *max\_features* features.

**max\_depth** : integer or None, optional (default=None)

The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than *min\_samples\_split* samples.

**min\_samples\_split** : int, float, optional (default=2)

The minimum number of samples required to split an internal node:

- If int, then consider *min\_samples\_split* as the minimum number.
- If float, then *min\_samples\_split* is a percentage and  $\text{ceil}(\text{min\_samples\_split} * \text{n\_samples})$  are the minimum number of samples for each split.

Changed in version 0.18: Added float values for percentages.

**min\_samples\_leaf** : int, float, optional (default=1)

The minimum number of samples required to be at a leaf node:

- If int, then consider *min\_samples\_leaf* as the minimum number.
- If float, then *min\_samples\_leaf* is a percentage and  $\text{ceil}(\text{min\_samples\_leaf} * n_{\text{samples}})$  are the minimum number of samples for each node.

Changed in version 0.18: Added float values for percentages.

**min\_weight\_fraction\_leaf** : float, optional (default=0.)

The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when *sample\_weight* is not provided.

**max\_leaf\_nodes** : int or None, optional (default=None)

Grow trees with *max\_leaf\_nodes* in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

**min\_impurity\_split** : float,

Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: *min\_impurity\_split* has been deprecated in favor of *min\_impurity\_decrease* in 0.19 and will be removed in 0.21. Use *min\_impurity\_decrease* instead.

**min\_impurity\_decrease** : float, optional (default=0.)

A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

$$\frac{N_t}{N} \cdot (\text{impurity} - \frac{N_t.R}{N_t} \cdot \text{right\_impurity} - \frac{N_t.L}{N_t} \cdot \text{left\_impurity})$$

where *N* is the total number of samples, *N<sub>t</sub>* is the number of samples at the current node, *N<sub>t</sub>.L* is the number of samples in the left child, and *N<sub>t</sub>.R* is the number of samples in the right child.

*N*, *N<sub>t</sub>*, *N<sub>t</sub>.R* and *N<sub>t</sub>.L* all refer to the weighted sum, if *sample\_weight* is passed.

New in version 0.19.

**bootstrap** : boolean, optional (default=False)

Whether bootstrap samples are used when building trees.

**oob\_score** : bool, optional (default=False)

Whether to use out-of-bag samples to estimate the generalization accuracy.

**n\_jobs** : integer, optional (default=1)

The number of jobs to run in parallel for both *fit* and *predict*. If -1, then the number of jobs is set to the number of cores.

**random\_state** : int, RandomState instance or None, optional (default=None)

If int, `random_state` is the seed used by the random number generator; If `RandomState` instance, `random_state` is the random number generator; If None, the random number generator is the `RandomState` instance used by `np.random`.

**verbose** : int, optional (default=0)

Controls the verbosity of the tree building process.

**warm\_start** : bool, optional (default=False)

When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest.

**class\_weight** : dict, list of dicts, “balanced”, “balanced\_subsample” or None, optional (default=None)

Weights associated with classes in the form `{class_label: weight}`. If not given, all classes are supposed to have weight one. For multi-output problems, a list of dicts can be provided in the same order as the columns of `y`.

Note that for multioutput (including multilabel) weights should be defined for each class of every column in its own dict. For example, for four-class multilabel classification weights should be `[{0: 1, 1: 1}, {0: 1, 1: 5}, {0: 1, 1: 1}, {0: 1, 1: 1}]` instead of `[{1:1}, {2:5}, {3:1}, {4:1}]`.

The “balanced” mode uses the values of `y` to automatically adjust weights inversely proportional to class frequencies in the input data as `n_samples / (n_classes * np.bincount(y))`

The “balanced\_subsample” mode is the same as “balanced” except that weights are computed based on the bootstrap sample for every tree grown.

For multi-output, the weights of each column of `y` will be multiplied.

Note that these weights will be multiplied with `sample_weight` (passed through the `fit` method) if `sample_weight` is specified.

**Attributes** `estimators_` : list of `DecisionTreeClassifier`

The collection of fitted sub-estimators.

`classes_` : array of shape = [n\_classes] or a list of such arrays

The classes labels (single output problem), or a list of arrays of class labels (multi-output problem).

`n_classes_` : int or list

The number of classes (single output problem), or a list containing the number of classes for each output (multi-output problem).

`feature_importances_` : array of shape = [n\_features]

The feature importances (the higher, the more important the feature).

`n_features_` : int

The number of features when `fit` is performed.

`n_outputs_` : int

The number of outputs when `fit` is performed.

`oob_score_` : float

Score of the training dataset obtained using an out-of-bag estimate.

`oob_decision_function_` : array of shape = [n\_samples, n\_classes]

Decision function computed with out-of-bag estimate on the training set. If `n_estimators` is small it might be possible that a data point was never left out during the bootstrap. In this case, `oob_decision_function_` might contain NaN.

See also:

`sklearn.tree.ExtraTreeClassifier` Base classifier for this ensemble.

`RandomForestClassifier` Ensemble Classifier based on trees with optimal splits.

## Notes

The default values for the parameters controlling the size of the trees (e.g. `max_depth`, `min_samples_leaf`, etc.) lead to fully grown and unpruned trees which can potentially be very large on some data sets. To reduce memory consumption, the complexity and size of the trees should be controlled by setting those parameter values.

## Methods

<code>apply(X)</code>	Apply trees in the forest to X, return leaf indices.
<code>decision_path(X)</code>	Return the decision path in the forest
<code>fit(X, y[, sample_weight])</code>	Build a forest of trees from the training set (X, y).
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict class for X.
<code>predict_log_proba(X)</code>	Predict class log-probabilities for X.
<code>predict_proba(X)</code>	Predict class probabilities for X.
<code>score(X, y[, sample_weight])</code>	Returns the mean accuracy on the given test data and labels.
<code>set_params(**params)</code>	Set the parameters of this estimator.

`__init__(n_estimators=10, criterion='gini', max_depth=None, min_samples_split=2, min_samples_leaf=1, min_weight_fraction_leaf=0.0, max_features='auto', max_leaf_nodes=None, min_impurity_decrease=0.0, min_impurity_split=None, bootstrap=False, oob_score=False, n_jobs=1, random_state=None, verbose=0, warm_start=False, class_weight=None)`

`apply(X)`

Apply trees in the forest to X, return leaf indices.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `X_leaves` : array-like, shape = [n\_samples, n\_estimators]

For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

**decision\_path**(*X*)

Return the decision path in the forest

New in version 0.18.

**Parameters** *X* : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** *indicator* : sparse csr array, shape = [n\_samples, n\_nodes]

Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

*n\_nodes\_ptr* : array of size (n\_estimators + 1, )

The columns from *indicator*[*n\_nodes\_ptr*[*i*]:*n\_nodes\_ptr*[*i*+1]] gives the indicator value for the *i*-th estimator.

**feature\_importances\_**

**Return the feature importances (the higher, the more important the feature).**

**Returns** *feature\_importances\_* : array, shape = [n\_features]

**fit**(*X*, *y*, *sample\_weight=None*)

Build a forest of trees from the training set (*X*, *y*).

**Parameters** *X* : array-like or sparse matrix of shape = [n\_samples, n\_features]

The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

*y* : array-like, shape = [n\_samples] or [n\_samples, n\_outputs]

The target values (class labels in classification, real numbers in regression).

*sample\_weight* : array-like, shape = [n\_samples] or None

Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

**Returns** *self* : object

Returns self.

**get\_params**(*deep=True*)

Get parameters for this estimator.

**Parameters** *deep* : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** *params* : mapping of string to any

Parameter names mapped to their values.

**predict**(*X*)

Predict class for *X*.

The predicted class of an input sample is a vote by the trees in the forest, weighted by their probability estimates. That is, the predicted class is the one with highest mean probability estimate across the trees.

**Parameters** `X` : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `y` : array of shape = [n\_samples] or [n\_samples, n\_outputs]

The predicted classes.

**predict\_log\_proba** (`X`)

Predict class log-probabilities for `X`.

The predicted class log-probabilities of an input sample is computed as the log of the mean predicted class probabilities of the trees in the forest.

**Parameters** `X` : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `p` : array of shape = [n\_samples, n\_classes], or a list of n\_outputs

such arrays if `n_outputs > 1`. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute `classes_`.

**predict\_proba** (`X`)

Predict class probabilities for `X`.

The predicted class probabilities of an input sample are computed as the mean predicted class probabilities of the trees in the forest. The class probability of a single tree is the fraction of samples of the same class in a leaf.

**Parameters** `X` : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `p` : array of shape = [n\_samples, n\_classes], or a list of n\_outputs

such arrays if `n_outputs > 1`. The class probabilities of the input samples. The order of the classes corresponds to that in the attribute `classes_`.

**score** (`X, y, sample_weight=None`)

Returns the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

**Parameters** `X` : array-like, shape = (n\_samples, n\_features)

Test samples.

`y` : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True labels for `X`.

`sample_weight` : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** `score` : float

Mean accuracy of `self.predict(X)` wrt. `y`.

---

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

**Returns self :**

### sklearn.ensemble.ExtraTreesRegressor

```
class sklearn.ensemble.ExtraTreesRegressor(n_estimators=10,          criti-
                                           rion='mse',                  max_depth=None,
                                           min_samples_split=2,        min_samples_leaf=1,
                                           min_weight_fraction_leaf=0.0,
                                           max_features='auto',       max_leaf_nodes=None,
                                           min_impurity_decrease=0.0,
                                           min_impurity_split=None,    bootstrap=False,
                                           oob_score=False,            n_jobs=1,
                                           random_state=None,          verbose=0,
                                           warm_start=False)
```

An extra-trees regressor.

This class implements a meta estimator that fits a number of randomized decision trees (a.k.a. extra-trees) on various sub-samples of the dataset and use averaging to improve the predictive accuracy and control over-fitting.

Read more in the [User Guide](#).

**Parameters** `n_estimators` : integer, optional (default=10)

The number of trees in the forest.

`criterion` : string, optional (default="mse")

The function to measure the quality of a split. Supported criteria are "mse" for the mean squared error, which is equal to variance reduction as feature selection criterion, and "mae" for the mean absolute error.

New in version 0.18: Mean Absolute Error (MAE) criterion.

`max_features` : int, float, string or None, optional (default="auto")

The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.
- If float, then `max_features` is a percentage and `int(max_features * n_features)` features are considered at each split.
- If "auto", then `max_features=n_features`.

- If “sqrt”, then  $\max\_features = \sqrt{n\_features}$ .
- If “log2”, then  $\max\_features = \log_2(n\_features)$ .
- If None, then  $\max\_features = n\_features$ .

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

**max\_depth** : integer or None, optional (default=None)

The maximum depth of the tree. If None, then nodes are expanded until all leaves are pure or until all leaves contain less than `min_samples_split` samples.

**min\_samples\_split** : int, float, optional (default=2)

The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.
- If float, then `min_samples_split` is a percentage and  $\text{ceil}(\min\_samples\_split * n\_samples)$  are the minimum number of samples for each split.

Changed in version 0.18: Added float values for percentages.

**min\_samples\_leaf** : int, float, optional (default=1)

The minimum number of samples required to be at a leaf node:

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a percentage and  $\text{ceil}(\min\_samples\_leaf * n\_samples)$  are the minimum number of samples for each node.

Changed in version 0.18: Added float values for percentages.

**min\_weight\_fraction\_leaf** : float, optional (default=0.)

The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when `sample_weight` is not provided.

**max\_leaf\_nodes** : int or None, optional (default=None)

Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

**min\_impurity\_split** : float,

Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19 and will be removed in 0.21. Use `min_impurity_decrease` instead.

**min\_impurity\_decrease** : float, optional (default=0.)

A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

$$\frac{N_t}{N} * (\text{impurity} - \frac{N_{t,R}}{N_t} * \text{right\_impurity} - \frac{N_{t,L}}{N_t} * \text{left\_impurity})$$

where  $N$  is the total number of samples,  $N_t$  is the number of samples at the current node,  $N_{t\_L}$  is the number of samples in the left child, and  $N_{t\_R}$  is the number of samples in the right child.

$N$ ,  $N_t$ ,  $N_{t\_R}$  and  $N_{t\_L}$  all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

**bootstrap** : boolean, optional (default=False)

Whether bootstrap samples are used when building trees.

**oob\_score** : bool, optional (default=False)

Whether to use out-of-bag samples to estimate the  $R^2$  on unseen data.

**n\_jobs** : integer, optional (default=1)

The number of jobs to run in parallel for both `fit` and `predict`. If -1, then the number of jobs is set to the number of cores.

**random\_state** : int, RandomState instance or None, optional (default=None)

If int, `random_state` is the seed used by the random number generator; If RandomState instance, `random_state` is the random number generator; If None, the random number generator is the RandomState instance used by `np.random`.

**verbose** : int, optional (default=0)

Controls the verbosity of the tree building process.

**warm\_start** : bool, optional (default=False)

When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just fit a whole new forest.

**Attributes** `estimators_` : list of DecisionTreeRegressor

The collection of fitted sub-estimators.

`feature_importances_` : array of shape = [n\_features]

The feature importances (the higher, the more important the feature).

`n_features_` : int

The number of features.

`n_outputs_` : int

The number of outputs.

`oob_score_` : float

Score of the training dataset obtained using an out-of-bag estimate.

`oob_prediction_` : array of shape = [n\_samples]

Prediction computed with out-of-bag estimate on the training set.

### `apply(X)`

Apply trees in the forest to X, return leaf indices.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `X_leaves` : array\_like, shape = [n\_samples, n\_estimators]

For each datapoint x in X and for each tree in the forest, return the index of the leaf x ends up in.

### `decision_path(X)`

Return the decision path in the forest

New in version 0.18.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** `indicator` : sparse csr array, shape = [n\_samples, n\_nodes]

Return a node indicator matrix where non zero elements indicates that the samples goes through the nodes.

**n\_nodes\_ptr** : array of size (n\_estimators + 1, )

The columns from indicator[n\_nodes\_ptr[i]:n\_nodes\_ptr[i+1]] gives the indicator value for the i-th estimator.

#### **feature\_importances\_**

Return the feature importances (the higher, the more important the feature).

**Returns** **feature\_importances\_** : array, shape = [n\_features]

#### **fit** (*X*, *y*, *sample\_weight=None*)

Build a forest of trees from the training set (*X*, *y*).

**Parameters** **X** : array-like or sparse matrix of shape = [n\_samples, n\_features]

The training input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csc_matrix`.

**y** : array-like, shape = [n\_samples] or [n\_samples, n\_outputs]

The target values (class labels in classification, real numbers in regression).

**sample\_weight** : array-like, shape = [n\_samples] or None

Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

**Returns** **self** : object

Returns self.

#### **get\_params** (*deep=True*)

Get parameters for this estimator.

**Parameters** **deep** : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** **params** : mapping of string to any

Parameter names mapped to their values.

#### **predict** (*X*)

Predict regression target for *X*.

The predicted regression target of an input sample is computed as the mean predicted regression targets of the trees in the forest.

**Parameters** **X** : array-like or sparse matrix of shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted into a sparse `csr_matrix`.

**Returns** **y** : array of shape = [n\_samples] or [n\_samples, n\_outputs]

The predicted values.

#### **score** (*X*, *y*, *sample\_weight=None*)

Returns the coefficient of determination R^2 of the prediction.

The coefficient R<sup>2</sup> is defined as  $(1 - u/v)$ , where  $u$  is the residual sum of squares  $((y_{true} - y_{pred})^2).sum()$  and  $v$  is the total sum of squares  $((y_{true} - y_{true}.mean())^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of  $y$ , disregarding the input features, would get a R<sup>2</sup> score of 0.0.

**Parameters** `X` : array-like, shape = (n\_samples, n\_features)

Test samples.

`y` : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for `X`.

`sample_weight` : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** `score` : float

R<sup>2</sup> of self.predict(`X`) wrt. `y`.

**set\_params** (\*\*params)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** `self`:

## Examples using `sklearn.ensemble.ExtraTreesRegressor`

- Face completion with a multi-output estimators
- Sparse recovery: feature selection for sparse linear models

## sklearn.ensemble.GradientBoostingClassifier

```
class sklearn.ensemble.GradientBoostingClassifier(loss='deviance', learning_rate=0.1,
                                                 n_estimators=100, subsample=1.0,
                                                 criterion='friedman_mse',
                                                 min_samples_split=2,
                                                 min_samples_leaf=1,
                                                 min_weight_fraction_leaf=0.0,
                                                 max_depth=3,
                                                 min_impurity_decrease=0.0,
                                                 min_impurity_split=None,
                                                 init=None, random_state=None,
                                                 max_features=None, verbose=0,
                                                 max_leaf_nodes=None,
                                                 warm_start=False, presort='auto')
```

Gradient Boosting for classification.

GB builds an additive model in a forward stage-wise fashion; it allows for the optimization of arbitrary differentiable loss functions. In each stage n\_classes\_ regression trees are fit on the negative gradient of the binomial or multinomial deviance loss function. Binary classification is a special case where only a single regression tree is induced.

Read more in the [User Guide](#).

**Parameters** `loss` : {‘deviance’, ‘exponential’}, optional (default=’deviance’)

loss function to be optimized. ‘deviance’ refers to deviance (= logistic regression) for classification with probabilistic outputs. For loss ‘exponential’ gradient boosting recovers the AdaBoost algorithm.

`learning_rate` : float, optional (default=0.1)

learning rate shrinks the contribution of each tree by *learning\_rate*. There is a trade-off between learning\_rate and n\_estimators.

`n_estimators` : int (default=100)

The number of boosting stages to perform. Gradient boosting is fairly robust to overfitting so a large number usually results in better performance.

`max_depth` : integer, optional (default=3)

maximum depth of the individual regression estimators. The maximum depth limits the number of nodes in the tree. Tune this parameter for best performance; the best value depends on the interaction of the input variables.

`criterion` : string, optional (default=”friedman\_mse”)

The function to measure the quality of a split. Supported criteria are “friedman\_mse” for the mean squared error with improvement score by Friedman, “mse” for mean squared error, and “mae” for the mean absolute error. The default value of “friedman\_mse” is generally the best as it can provide a better approximation in some cases.

New in version 0.18.

`min_samples_split` : int, float, optional (default=2)

The minimum number of samples required to split an internal node:

- If int, then consider `min_samples_split` as the minimum number.
- If float, then `min_samples_split` is a percentage and  $\text{ceil}(\text{min\_samples\_split} * n_{\text{samples}})$  are the minimum number of samples for each split.

Changed in version 0.18: Added float values for percentages.

`min_samples_leaf` : int, float, optional (default=1)

The minimum number of samples required to be at a leaf node:

- If int, then consider `min_samples_leaf` as the minimum number.
- If float, then `min_samples_leaf` is a percentage and  $\text{ceil}(\text{min\_samples\_leaf} * n_{\text{samples}})$  are the minimum number of samples for each node.

Changed in version 0.18: Added float values for percentages.

`min_weight_fraction_leaf` : float, optional (default=0.)

The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when sample\_weight is not provided.

`subsample` : float, optional (default=1.0)

The fraction of samples to be used for fitting the individual base learners. If smaller than 1.0 this results in Stochastic Gradient Boosting. `subsample` interacts with the parameter `n_estimators`. Choosing `subsample < 1.0` leads to a reduction of variance and an increase in bias.

**max\_features** : int, float, string or None, optional (default=None)

The number of features to consider when looking for the best split:

- If int, then consider  $\text{max\_features}$  features at each split.
- If float, then  $\text{max\_features}$  is a percentage and  $\text{int}(\text{max\_features} * n\_features)$  features are considered at each split.
- If “auto”, then  $\text{max\_features}=\sqrt{n\_features}$ .
- If “sqrt”, then  $\text{max\_features}=\sqrt{n\_features}$ .
- If “log2”, then  $\text{max\_features}=\log_2(n\_features)$ .
- If None, then  $\text{max\_features}=n\_features$ .

Choosing  $\text{max\_features} < n\_features$  leads to a reduction of variance and an increase in bias.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than  $\text{max\_features}$  features.

**max\_leaf\_nodes** : int or None, optional (default=None)

Grow trees with  $\text{max\_leaf\_nodes}$  in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

**min\_impurity\_split** : float,

Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19 and will be removed in 0.21. Use `min_impurity_decrease` instead.

**min\_impurity\_decrease** : float, optional (default=0.)

A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

$$\frac{N_t}{N} \cdot (\text{impurity} - \frac{N_{t\_R}}{N_t} \cdot \text{right\_impurity} - \frac{N_{t\_L}}{N_t} \cdot \text{left\_impurity})$$

where  $N$  is the total number of samples,  $N_t$  is the number of samples at the current node,  $N_{t\_L}$  is the number of samples in the left child, and  $N_{t\_R}$  is the number of samples in the right child.

$N$ ,  $N_t$ ,  $N_{t\_R}$  and  $N_{t\_L}$  all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

**init** : BaseEstimator, None, optional (default=None)

An estimator object that is used to compute the initial predictions. `init` has to provide `fit` and `predict`. If None it uses `loss.init_estimator`.

**verbose** : int, default: 0

Enable verbose output. If 1 then it prints progress and performance once in a while (the more trees the lower the frequency). If greater than 1 then it prints progress and performance for every tree.

**warm\_start** : bool, default: False

When set to True, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just erase the previous solution.

**random\_state** : int, RandomState instance or None, optional (default=None)

If int, random\_state is the seed used by the random number generator; If RandomState instance, random\_state is the random number generator; If None, the random number generator is the RandomState instance used by *np.random*.

**presort** : bool or ‘auto’, optional (default=‘auto’)

Whether to presort the data to speed up the finding of best splits in fitting. Auto mode by default will use presorting on dense data and default to normal sorting on sparse data. Setting presort to true on sparse data will raise an error.

New in version 0.17: *presort* parameter.

**Attributes** **feature\_importances\_** : array, shape = [n\_features]

The feature importances (the higher, the more important the feature).

**oob\_improvement\_** : array, shape = [n\_estimators]

The improvement in loss (= deviance) on the out-of-bag samples relative to the previous iteration. `oob_improvement_[0]` is the improvement in loss of the first stage over the `init` estimator.

**train\_score\_** : array, shape = [n\_estimators]

The i-th score `train_score_[i]` is the deviance (= loss) of the model at iteration `i` on the in-bag sample. If `subsample == 1` this is the deviance on the training data.

**loss\_** : LossFunction

The concrete `LossFunction` object.

**init** : BaseEstimator

The estimator that provides the initial predictions. Set via the `init` argument or `loss_.init_estimator`.

**estimators\_** : ndarray of DecisionTreeRegressor, shape = [n\_estimators, loss\_.K]

The collection of fitted sub-estimators. `loss_.K` is 1 for binary classification, otherwise `n_classes`.

[RandomForestClassifier](#),

## Notes

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data and `max_features=n_features`, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, `random_state` has to be fixed.

## Methods

<code>apply(X)</code>	Apply trees in the ensemble to X, return leaf indices.
<code>decision_function(X)</code>	Compute the decision function of X.
<code>fit(X, y[, sample_weight, monitor])</code>	Fit the gradient boosting model.
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict class for X.
<code>predict_log_proba(X)</code>	Predict class log-probabilities for X.
<code>predict_proba(X)</code>	Predict class probabilities for X.
<code>score(X, y[, sample_weight])</code>	Returns the mean accuracy on the given test data and labels.
<code>set_params(**params)</code>	Set the parameters of this estimator.
<code>staged_decision_function(X)</code>	Compute decision function of X for each iteration.
<code>staged_predict(X)</code>	Predict class at each stage for X.
<code>staged_predict_proba(X)</code>	Predict class probabilities at each stage for X.

```
__init__(loss='deviance', learning_rate=0.1, n_estimators=100, subsample=1.0,
         criterion='friedman_mse', min_samples_split=2, min_samples_leaf=1,
         min_weight_fraction_leaf=0.0, max_depth=3, min_impurity_decrease=0.0,
         min_impurity_split=None, init=None, random_state=None, max_features=None, verbose=0, max_leaf_nodes=None, warm_start=False, presort='auto')
```

**apply (X)**  
Apply trees in the ensemble to X, return leaf indices.

New in version 0.17.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted to a sparse `csr_matrix`.

**Returns** `X_leaves` : array\_like, shape = [n\_samples, n\_estimators, n\_classes]

For each datapoint x in X and for each tree in the ensemble, return the index of the leaf x ends up in each estimator. In the case of binary classification n\_classes is 1.

**decision\_function (X)**  
Compute the decision function of X.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** `score` : array, shape = [n\_samples, n\_classes] or [n\_samples]

The decision function of the input samples. The order of the classes corresponds to that in the attribute `classes_`. Regression and binary classification produce an array of shape [n\_samples].

#### `feature_importances_`

**Return the feature importances (the higher, the more important the feature).**

**Returns** `feature_importances_` : array, shape = [n\_features]

#### `fit (X, y, sample_weight=None, monitor=None)`

Fit the gradient boosting model.

**Parameters** `X` : array-like, shape = [n\_samples, n\_features]

Training vectors, where n\_samples is the number of samples and n\_features is the number of features.

`y` : array-like, shape = [n\_samples]

Target values (integers in classification, real numbers in regression) For classification, labels must correspond to classes.

`sample_weight` : array-like, shape = [n\_samples] or None

Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

`monitor` : callable, optional

The monitor is called after each iteration with the current iteration, a reference to the estimator and the local variables of `_fit_stages` as keyword arguments `callable(i, self, locals())`. If the callable returns True the fitting procedure is stopped. The monitor can be used for various things such as computing held-out estimates, early stopping, model introspect, and snapshotting.

**Returns** `self` : object

Returns self.

#### `get_params (deep=True)`

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** `params` : mapping of string to any

Parameter names mapped to their values.

#### `n_features`

DEPRECATED: Attribute `n_features` was deprecated in version 0.19 and will be removed in 0.21.

#### `predict (X)`

Predict class for X.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** `y` : array of shape = [”n\_samples]

The predicted values.

**predict\_log\_proba** (`X`)

Predict class log-probabilities for `X`.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** `p` : array of shape = [n\_samples]

The class log-probabilities of the input samples. The order of the classes corresponds to that in the attribute `classes_`.

**Raises** `AttributeError` :

If the `loss` does not support probabilities.

**predict\_proba** (`X`)

Predict class probabilities for `X`.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** `p` : array of shape = [n\_samples]

The class probabilities of the input samples. The order of the classes corresponds to that in the attribute `classes_`.

**Raises** `AttributeError` :

If the `loss` does not support probabilities.

**score** (`X, y, sample_weight=None`)

Returns the mean accuracy on the given test data and labels.

In multi-label classification, this is the subset accuracy which is a harsh metric since you require for each sample that each label set be correctly predicted.

**Parameters** `X` : array-like, shape = (n\_samples, n\_features)

Test samples.

`y` : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True labels for `X`.

`sample_weight` : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** `score` : float

Mean accuracy of self.predict(`X`) wrt. `y`.

**set\_params** (\*\*`params`)

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form `<component>__<parameter>` so that it's possible to update each component of a nested object.

**Returns** `self` :

**staged\_decision\_function(X)**

Compute decision function of X for each iteration.

This method allows monitoring (i.e. determine error on testing set) after each stage.

**Parameters** **X** : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** **score** : generator of array, shape = [n\_samples, k]

The decision function of the input samples. The order of the classes corresponds to that in the attribute `classes_`. Regression and binary classification are special cases with `k == 1`, otherwise `k==n_classes`.

**staged\_predict(X)**

Predict class at each stage for X.

This method allows monitoring (i.e. determine error on testing set) after each stage.

**Parameters** **X** : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** **y** : generator of array of shape = [n\_samples]

The predicted value of the input samples.

**staged\_predict\_proba(X)**

Predict class probabilities at each stage for X.

This method allows monitoring (i.e. determine error on testing set) after each stage.

**Parameters** **X** : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** **y** : generator of array of shape = [n\_samples]

The predicted value of the input samples.

**Examples using `sklearn.ensemble.GradientBoostingClassifier`**

- *Gradient Boosting Out-of-Bag estimates*
- *Gradient Boosting regularization*

**sklearn.ensemble.GradientBoostingRegressor**

```
class sklearn.ensemble.GradientBoostingRegressor(loss='ls',           learning_rate=0.1,
                                                n_estimators=100,         subsam-
                                                ple=1.0,             criterion='friedman_mse',
                                                min_samples_split=2,
                                                min_samples_leaf=1,
                                                min_weight_fraction_leaf=0.0,
                                                max_depth=3,
                                                min_impurity_decrease=0.0,
                                                min_impurity_split=None,
                                                init=None,            random_state=None,
                                                max_features=None,     alpha=0.9,
                                                verbose=0,            max_leaf_nodes=None,
                                                warm_start=False,      presort='auto')
```

Gradient Boosting for regression.

GB builds an additive model in a forward stage-wise fashion; it allows for the optimization of arbitrary differentiable loss functions. In each stage a regression tree is fit on the negative gradient of the given loss function.

Read more in the [User Guide](#).

**Parameters** **loss** : {‘ls’, ‘lad’, ‘huber’, ‘quantile’}, optional (default=‘ls’)

loss function to be optimized. ‘ls’ refers to least squares regression. ‘lad’ (least absolute deviation) is a highly robust loss function solely based on order information of the input variables. ‘huber’ is a combination of the two. ‘quantile’ allows quantile regression (use *alpha* to specify the quantile).

**learning\_rate** : float, optional (default=0.1)

learning rate shrinks the contribution of each tree by *learning\_rate*. There is a trade-off between learning\_rate and n\_estimators.

**n\_estimators** : int (default=100)

The number of boosting stages to perform. Gradient boosting is fairly robust to overfitting so a large number usually results in better performance.

**max\_depth** : integer, optional (default=3)

maximum depth of the individual regression estimators. The maximum depth limits the number of nodes in the tree. Tune this parameter for best performance; the best value depends on the interaction of the input variables.

**criterion** : string, optional (default=“friedman\_mse”)

The function to measure the quality of a split. Supported criteria are “friedman\_mse” for the mean squared error with improvement score by Friedman, “mse” for mean squared error, and “mae” for the mean absolute error. The default value of “friedman\_mse” is generally the best as it can provide a better approximation in some cases.

New in version 0.18.

**min\_samples\_split** : int, float, optional (default=2)

The minimum number of samples required to split an internal node:

- If int, then consider *min\_samples\_split* as the minimum number.
- If float, then *min\_samples\_split* is a percentage and  $\text{ceil}(\text{min\_samples\_split} * \text{n\_samples})$  are the minimum number of samples for each split.

Changed in version 0.18: Added float values for percentages.

**min\_samples\_leaf** : int, float, optional (default=1)

The minimum number of samples required to be at a leaf node:

- If int, then consider  $\text{min\_samples\_leaf}$  as the minimum number.
- If float, then  $\text{min\_samples\_leaf}$  is a percentage and  $\text{ceil}(\text{min\_samples\_leaf} * n_{\text{samples}})$  are the minimum number of samples for each node.

Changed in version 0.18: Added float values for percentages.

**min\_weight\_fraction\_leaf** : float, optional (default=0.)

The minimum weighted fraction of the sum total of weights (of all the input samples) required to be at a leaf node. Samples have equal weight when `sample_weight` is not provided.

**subsample** : float, optional (default=1.0)

The fraction of samples to be used for fitting the individual base learners. If smaller than 1.0 this results in Stochastic Gradient Boosting. `subsample` interacts with the parameter `n_estimators`. Choosing  $\text{subsample} < 1.0$  leads to a reduction of variance and an increase in bias.

**max\_features** : int, float, string or None, optional (default=None)

The number of features to consider when looking for the best split:

- If int, then consider `max_features` features at each split.
- If float, then `max_features` is a percentage and  $\text{int}(\text{max\_features} * n_{\text{features}})$  features are considered at each split.
- If “auto”, then `max_features=n_features`.
- If “sqrt”, then `max_features=sqrt(n_features)`.
- If “log2”, then `max_features=log2(n_features)`.
- If None, then `max_features=n_features`.

Choosing  $\text{max\_features} < n_{\text{features}}$  leads to a reduction of variance and an increase in bias.

Note: the search for a split does not stop until at least one valid partition of the node samples is found, even if it requires to effectively inspect more than `max_features` features.

**max\_leaf\_nodes** : int or None, optional (default=None)

Grow trees with `max_leaf_nodes` in best-first fashion. Best nodes are defined as relative reduction in impurity. If None then unlimited number of leaf nodes.

**min\_impurity\_split** : float,

Threshold for early stopping in tree growth. A node will split if its impurity is above the threshold, otherwise it is a leaf.

Deprecated since version 0.19: `min_impurity_split` has been deprecated in favor of `min_impurity_decrease` in 0.19 and will be removed in 0.21. Use `min_impurity_decrease` instead.

**min\_impurity\_decrease** : float, optional (default=0.)

A node will be split if this split induces a decrease of the impurity greater than or equal to this value.

The weighted impurity decrease equation is the following:

$$\begin{aligned} & N_t / N * (\text{impurity} - N_{t\_R} / N_t * \text{right\_impurity} \\ & - N_{t\_L} / N_t * \text{left\_impurity}) \end{aligned}$$

where  $N$  is the total number of samples,  $N_t$  is the number of samples at the current node,  $N_{t\_L}$  is the number of samples in the left child, and  $N_{t\_R}$  is the number of samples in the right child.

$N$ ,  $N_t$ ,  $N_{t\_R}$  and  $N_{t\_L}$  all refer to the weighted sum, if `sample_weight` is passed.

New in version 0.19.

**alpha** : float (default=0.9)

The alpha-quantile of the huber loss function and the quantile loss function. Only if `loss='huber'` or `loss='quantile'`.

**init** : BaseEstimator, None, optional (default=None)

An estimator object that is used to compute the initial predictions. `init` has to provide `fit` and `predict`. If `None` it uses `loss.init_estimator`.

**verbose** : int, default: 0

Enable verbose output. If 1 then it prints progress and performance once in a while (the more trees the lower the frequency). If greater than 1 then it prints progress and performance for every tree.

**warm\_start** : bool, default: False

When set to `True`, reuse the solution of the previous call to fit and add more estimators to the ensemble, otherwise, just erase the previous solution.

**random\_state** : int, RandomState instance or None, optional (default=None)

If int, `random_state` is the seed used by the random number generator; If `RandomState` instance, `random_state` is the random number generator; If `None`, the random number generator is the `RandomState` instance used by `np.random`.

**presort** : bool or ‘auto’, optional (default=’auto’)

Whether to presort the data to speed up the finding of best splits in fitting. Auto mode by default will use presorting on dense data and default to normal sorting on sparse data. Setting presort to true on sparse data will raise an error.

New in version 0.17: optional parameter `presort`.

**Attributes** `feature_importances_` : array, shape = [n\_features]

The feature importances (the higher, the more important the feature).

`oob_improvement_` : array, shape = [n\_estimators]

The improvement in loss (= deviance) on the out-of-bag samples relative to the previous iteration. `oob_improvement_[0]` is the improvement in loss of the first stage over the `init` estimator.

`train_score_` : array, shape = [n\_estimators]

The i-th score `train_score_[i]` is the deviance (= loss) of the model at iteration i on the in-bag sample. If `subsample == 1` this is the deviance on the training data.

**loss\_** : LossFunction

The concrete `LossFunction` object.

**init** : BaseEstimator

The estimator that provides the initial predictions. Set via the `init` argument or `loss_.init_estimator`.

**estimators\_** : ndarray of DecisionTreeRegressor, shape = [n\_estimators, 1]

The collection of fitted sub-estimators.

#### See also:

`DecisionTreeRegressor`, `RandomForestRegressor`

### Notes

The features are always randomly permuted at each split. Therefore, the best found split may vary, even with the same training data and `max_features=n_features`, if the improvement of the criterion is identical for several splits enumerated during the search of the best split. To obtain a deterministic behaviour during fitting, `random_state` has to be fixed.

### Methods

<code>apply(X)</code>	Apply trees in the ensemble to X, return leaf indices.
<code>fit(X, y[, sample_weight, monitor])</code>	Fit the gradient boosting model.
<code>get_params([deep])</code>	Get parameters for this estimator.
<code>predict(X)</code>	Predict regression target for X.
<code>score(X, y[, sample_weight])</code>	Returns the coefficient of determination R^2 of the prediction.
<code>set_params(**params)</code>	Set the parameters of this estimator.
<code>staged_predict(X)</code>	Predict regression target at each stage for X.

```
__init__(loss='ls', learning_rate=0.1, n_estimators=100, subsample=1.0, criterion='friedman_mse', min_samples_split=2, min_samples_leaf=1, min_weight_fraction_leaf=0.0, max_depth=3, min_impurity_decrease=0.0, min_impurity_split=None, init=None, random_state=None, max_features=None, alpha=0.9, verbose=0, max_leaf_nodes=None, warm_start=False, presort='auto')
```

`apply(X)`

Apply trees in the ensemble to X, return leaf indices.

New in version 0.17.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, its dtype will be converted to `dtype=np.float32`. If a sparse matrix is provided, it will be converted to a sparse `csr_matrix`.

**Returns** `X_leaves` : array\_like, shape = [n\_samples, n\_estimators]

For each datapoint `x` in `X` and for each tree in the ensemble, return the index of the leaf `x` ends up in each estimator.

**feature\_importances\_**

Return the feature importances (the higher, the more important the feature).

**Returns** `feature_importances_` : array, shape = [n\_features]

**fit** (`X, y, sample_weight=None, monitor=None`)

Fit the gradient boosting model.

**Parameters** `X` : array-like, shape = [n\_samples, n\_features]

Training vectors, where `n_samples` is the number of samples and `n_features` is the number of features.

`y` : array-like, shape = [n\_samples]

Target values (integers in classification, real numbers in regression) For classification, labels must correspond to classes.

`sample_weight` : array-like, shape = [n\_samples] or None

Sample weights. If None, then samples are equally weighted. Splits that would create child nodes with net zero or negative weight are ignored while searching for a split in each node. In the case of classification, splits are also ignored if they would result in any single class carrying a negative weight in either child node.

`monitor` : callable, optional

The monitor is called after each iteration with the current iteration, a reference to the estimator and the local variables of `_fit_stages` as keyword arguments `callable(i, self, locals())`. If the callable returns `True` the fitting procedure is stopped. The monitor can be used for various things such as computing held-out estimates, early stopping, model introspect, and snapshoting.

**Returns** `self` : object

Returns self.

**get\_params** (`deep=True`)

Get parameters for this estimator.

**Parameters** `deep` : boolean, optional

If True, will return the parameters for this estimator and contained subobjects that are estimators.

**Returns** `params` : mapping of string to any

Parameter names mapped to their values.

**n\_features**

DEPRECATED: Attribute `n_features` was deprecated in version 0.19 and will be removed in 0.21.

**`predict(X)`**

Predict regression target for X.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** `y` : array of shape = [n\_samples]

The predicted values.

**`score(X, y, sample_weight=None)`**

Returns the coefficient of determination R<sup>2</sup> of the prediction.

The coefficient R<sup>2</sup> is defined as  $(1 - u/v)$ , where  $u$  is the residual sum of squares  $((y_{\text{true}} - y_{\text{pred}})^2).sum()$  and  $v$  is the total sum of squares  $((y_{\text{true}} - y_{\text{true}.mean()})^2).sum()$ . The best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R<sup>2</sup> score of 0.0.

**Parameters** `X` : array-like, shape = (n\_samples, n\_features)

Test samples.

`y` : array-like, shape = (n\_samples) or (n\_samples, n\_outputs)

True values for X.

`sample_weight` : array-like, shape = [n\_samples], optional

Sample weights.

**Returns** `score` : float

R<sup>2</sup> of self.predict(X) wrt. y.

**`set_params(**params)`**

Set the parameters of this estimator.

The method works on simple estimators as well as on nested objects (such as pipelines). The latter have parameters of the form <component>\_\_<parameter> so that it's possible to update each component of a nested object.

**Returns** `self` :

**`staged_predict(X)`**

Predict regression target at each stage for X.

This method allows monitoring (i.e. determine error on testing set) after each stage.

**Parameters** `X` : array-like or sparse matrix, shape = [n\_samples, n\_features]

The input samples. Internally, it will be converted to `dtype=np.float32` and if a sparse matrix is provided to a sparse `csr_matrix`.

**Returns** `y` : generator of array of shape = [n\_samples]

The predicted value of the input samples.

### 3.3.3 Model evaluation: quantifying the quality of predictions

There are 3 different approaches to evaluate the quality of predictions of a model:

- **Estimator score method:** Estimators have a `score` method providing a default evaluation criterion for the problem they are designed to solve. This is not discussed on this page, but in each estimator's documentation.
- **Scoring parameter:** Model-evaluation tools using `cross-validation` (such as `model_selection.cross_val_score` and `model_selection.GridSearchCV`) rely on an internal `scoring` strategy. This is discussed in the section [The scoring parameter: defining model evaluation rules](#).
- **Metric functions:** The `metrics` module implements functions assessing prediction error for specific purposes. These metrics are detailed in sections on [Classification metrics](#), [Multilabel ranking metrics](#), [Regression metrics](#) and [Clustering metrics](#).

Finally, [Dummy estimators](#) are useful to get a baseline value of those metrics for random predictions.

**See also:**

For “pairwise” metrics, between *samples* and not estimators or predictions, see the [Pairwise metrics, Affinities and Kernels](#) section.

#### The scoring parameter: defining model evaluation rules

Model selection and evaluation using tools, such as `model_selection.GridSearchCV` and `model_selection.cross_val_score`, take a `scoring` parameter that controls what metric they apply to the estimators evaluated.

#### Common cases: predefined values

For the most common use cases, you can designate a scorer object with the `scoring` parameter; the table below shows all possible values. All scorer objects follow the convention that **higher return values are better than lower return values**. Thus metrics which measure the distance between the model and the data, like `metrics.mean_squared_error`, are available as `neg_mean_squared_error` which return the negated value of the metric.

Scoring	Function	Comment
<b>Classification</b>		
‘accuracy’	<code>metrics.accuracy_score</code>	
‘average_precision’	<code>metrics.average_precision_score</code>	
‘f1’	<code>metrics.f1_score</code>	for binary targets
‘f1_micro’	<code>metrics.f1_score</code>	micro-averaged
‘f1_macro’	<code>metrics.f1_score</code>	macro-averaged
‘f1_weighted’	<code>metrics.f1_score</code>	weighted average
‘f1_samples’	<code>metrics.f1_score</code>	by multilabel sample
‘neg_log_loss’	<code>metrics.log_loss</code>	requires predict_proba support
‘precision’ etc.	<code>metrics.precision_score</code>	suffixes apply as with ‘f1’
‘recall’ etc.	<code>metrics.recall_score</code>	suffixes apply as with ‘f1’
‘roc_auc’	<code>metrics.roc_auc_score</code>	
<b>Clustering</b>		
‘adjusted_rand_score’	<code>metrics.adjusted_rand_score</code>	
<b>Regression</b>		
‘neg_mean_absolute_error’	<code>metrics.mean_absolute_error</code>	
‘neg_mean_squared_error’	<code>metrics.mean_squared_error</code>	
‘neg_mean_squared_log_error’	<code>metrics.mean_squared_log_error</code>	
‘neg_median_absolute_error’	<code>metrics.median_absolute_error</code>	
‘r2’	<code>metrics.r2_score</code>	

Usage examples:

```
>>> from sklearn import svm, datasets
>>> from sklearn.model_selection import cross_val_score
>>> iris = datasets.load_iris()
>>> X, y = iris.data, iris.target
>>> clf = svm.SVC(probability=True, random_state=0)
>>> cross_val_score(clf, X, y, scoring='neg_log_loss')
array([-0.07..., -0.16..., -0.06...])
>>> model = svm.SVC()
>>> cross_val_score(model, X, y, scoring='wrong_choice')
Traceback (most recent call last):
ValueError: 'wrong_choice' is not a valid scoring value. Valid options are ['accuracy',
 'adjusted_mutual_info_score', 'adjusted_rand_score', 'average_precision',
 'completeness_score', 'f1', 'f1_macro', 'f1_micro', 'f1_samples', 'f1_weighted',
 'fowlkes_mallows_score', 'homogeneity_score', 'mutual_info_score', 'neg_log_loss',
 'neg_mean_absolute_error', 'neg_mean_squared_error', 'neg_mean_squared_log_error',
 'neg_median_absolute_error', 'normalized_mutual_info_score', 'precision',
 'precision_macro', 'precision_micro', 'precision_samples', 'precision_weighted', 'r2',
 'recall', 'recall_macro', 'recall_micro', 'recall_samples', 'recall_weighted',
 'roc_auc', 'v_measure_score']
```

---

**Note:** The values listed by the ValueError exception correspond to the functions measuring prediction accuracy described in the following sections. The scorer objects for those functions are stored in the dictionary `sklearn.metrics.SCORERS`.

---

## Defining your scoring strategy from metric functions

The module `sklearn.metric` also exposes a set of simple functions measuring a prediction error given ground truth and prediction:

- functions ending with `_score` return a value to maximize, the higher the better.
- functions ending with `_error` or `_loss` return a value to minimize, the lower the better. When converting into a scorer object using `make_scoring`, set the `greater_is_better` parameter to False (True by default; see the parameter description below).

Metrics available for various machine learning tasks are detailed in sections below.

Many metrics are not given names to be used as `scoring` values, sometimes because they require additional parameters, such as `fbeta_score`. In such cases, you need to generate an appropriate scoring object. The simplest way to generate a callable object for scoring is by using `make_scoring`. That function converts metrics into callables that can be used for model evaluation.

One typical use case is to wrap an existing metric function from the library with non-default values for its parameters, such as the `beta` parameter for the `fbeta_score` function:

```
>>> from sklearn.metrics import fbeta_score, make_scoring
>>> ftwo_scoring = make_scoring(fbeta_score, beta=2)
>>> from sklearn.model_selection import GridSearchCV
>>> from sklearn.svm import LinearSVC
>>> grid = GridSearchCV(LinearSVC(), param_grid={'C': [1, 10]}, scoring=ftwo_scoring)
```

The second use case is to build a completely custom scorer object from a simple python function using `make_scoring`, which can take several parameters:

- the python function you want to use (`my_custom_loss_func` in the example below)
- whether the python function returns a score (`greater_is_better=True`, the default) or a loss (`greater_is_better=False`). If a loss, the output of the python function is negated by the scorer object, conforming to the cross validation convention that scorers return higher values for better models.
- for classification metrics only: whether the python function you provided requires continuous decision certainties (`needs_threshold=True`). The default value is False.
- any additional parameters, such as `beta` or `labels` in `f1_score`.

Here is an example of building custom scorers, and of using the `greater_is_better` parameter:

```
>>> import numpy as np
>>> def my_custom_loss_func(ground_truth, predictions):
...     diff = np.abs(ground_truth - predictions).max()
...     return np.log(1 + diff)
...
>>> # loss_func will negate the return value of my_custom_loss_func,
>>> # which will be np.log(2), 0.693, given the values for ground_truth
>>> # and predictions defined below.
>>> loss = make_scoring(my_custom_loss_func, greater_is_better=False)
>>> score = make_scoring(my_custom_loss_func, greater_is_better=True)
>>> ground_truth = [[1], [1]]
>>> predictions = [0, 1]
>>> from sklearn.dummy import DummyClassifier
>>> clf = DummyClassifier(strategy='most_frequent', random_state=0)
>>> clf = clf.fit(ground_truth, predictions)
>>> loss(clf, ground_truth, predictions)
-0.69...
```

```
>>> score(clf, ground_truth, predictions)
0.69...
```

## Implementing your own scoring object

You can generate even more flexible model scorers by constructing your own scoring object from scratch, without using the `make_scoring` factory. For a callable to be a scorer, it needs to meet the protocol specified by the following two rules:

- It can be called with parameters `(estimator, X, y)`, where `estimator` is the model that should be evaluated, `X` is validation data, and `y` is the ground truth target for `X` (in the supervised case) or `None` (in the unsupervised case).
- It returns a floating point number that quantifies the `estimator` prediction quality on `X`, with reference to `y`. Again, by convention higher numbers are better, so if your scorer returns loss, that value should be negated.

## Classification metrics

The `sklearn.metrics` module implements several loss, score, and utility functions to measure classification performance. Some metrics might require probability estimates of the positive class, confidence values, or binary decisions values. Most implementations allow each sample to provide a weighted contribution to the overall score, through the `sample_weight` parameter.

Some of these are restricted to the binary classification case:

<code>matthews_corrcoef(y_true, y_pred[, ...])</code>	Compute the Matthews correlation coefficient (MCC) for binary classes
<code>precision_recall_curve(y_true, probas_pred)</code>	Compute precision-recall pairs for different probability thresholds
<code>roc_curve(y_true, y_score[, pos_label, ...])</code>	Compute Receiver operating characteristic (ROC)

Others also work in the multiclass case:

<code>cohen_kappa_score(y1, y2[, labels, weights, ...])</code>	Cohen's kappa: a statistic that measures inter-annotator agreement.
<code>confusion_matrix(y_true, y_pred[, labels, ...])</code>	Compute confusion matrix to evaluate the accuracy of a classification
<code>hinge_loss(y_true, pred_decision[, labels, ...])</code>	Average hinge loss (non-regularized)

Some also work in the multilabel case:

<code>accuracy_score(y_true, y_pred[, normalize, ...])</code>	Accuracy classification score.
<code>classification_report(y_true, y_pred[, ...])</code>	Build a text report showing the main classification metrics
<code>f1_score(y_true, y_pred[, labels, ...])</code>	Compute the F1 score, also known as balanced F-score or F-measure
<code>fbeta_score(y_true, y_pred, beta[, labels, ...])</code>	Compute the F-beta score
<code>hamming_loss(y_true, y_pred[, labels, ...])</code>	Compute the average Hamming loss.
<code>jaccard_similarity_score(y_true, y_pred[, ...])</code>	Jaccard similarity coefficient score
<code>log_loss(y_true, y_pred[, eps, normalize, ...])</code>	Log loss, aka logistic loss or cross-entropy loss.
<code>precision_recall_fscore_support(y_true, y_pred)</code>	Compute precision, recall, F-measure and support for each class

Continued on next page

Table 3.24 – continued from previous page

<code>precision_score(y_true, y_pred[, labels, ...])</code>	Compute the precision
<code>recall_score(y_true, y_pred[, labels, ...])</code>	Compute the recall
<code>zero_one_loss(y_true, y_pred[, normalize, ...])</code>	Zero-one classification loss.

And some work with binary and multilabel (but not multiclass) problems:

<code>average_precision_score(y_true, y_score[, ...])</code>	Compute average precision (AP) from prediction scores
<code>roc_auc_score(y_true, y_score[, average, ...])</code>	Compute Area Under the Curve (AUC) from prediction scores

In the following sub-sections, we will describe each of those functions, preceded by some notes on common API and metric definition.

## From binary to multiclass and multilabel

Some metrics are essentially defined for binary classification tasks (e.g. `f1_score`, `roc_auc_score`). In these cases, by default only the positive label is evaluated, assuming by default that the positive class is labelled 1 (though this may be configurable through the `pos_label` parameter). In extending a binary metric to multiclass or multilabel problems, the data is treated as a collection of binary problems, one for each class. There are then a number of ways to average binary metric calculations across the set of classes, each of which may be useful in some scenario. Where available, you should select among these using the `average` parameter.

- "macro" simply calculates the mean of the binary metrics, giving equal weight to each class. In problems where infrequent classes are nonetheless important, macro-averaging may be a means of highlighting their performance. On the other hand, the assumption that all classes are equally important is often untrue, such that macro-averaging will over-emphasize the typically low performance on an infrequent class.
- "weighted" accounts for class imbalance by computing the average of binary metrics in which each class's score is weighted by its presence in the true data sample.
- "micro" gives each sample-class pair an equal contribution to the overall metric (except as a result of sample-weight). Rather than summing the metric per class, this sums the dividends and divisors that make up the per-class metrics to calculate an overall quotient. Micro-averaging may be preferred in multilabel settings, including multiclass classification where a majority class is to be ignored.
- "samples" applies only to multilabel problems. It does not calculate a per-class measure, instead calculating the metric over the true and predicted classes for each sample in the evaluation data, and returning their (sample\_weight-weighted) average.
- Selecting `average=None` will return an array with the score for each class.

While multiclass data is provided to the metric, like binary targets, as an array of class labels, multilabel data is specified as an indicator matrix, in which cell  $[i, j]$  has value 1 if sample  $i$  has label  $j$  and value 0 otherwise.

## Accuracy score

The `accuracy_score` function computes the `accuracy`, either the fraction (default) or the count (`normalize=False`) of correct predictions.

In multilabel classification, the function returns the subset accuracy. If the entire set of predicted labels for a sample strictly match with the true set of labels, then the subset accuracy is 1.0; otherwise it is 0.0.

If  $\hat{y}_i$  is the predicted value of the  $i$ -th sample and  $y_i$  is the corresponding true value, then the fraction of correct predictions over  $n_{\text{samples}}$  is defined as

$$\text{accuracy}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} 1(\hat{y}_i = y_i)$$

where  $1(x)$  is the indicator function.

```
>>> import numpy as np
>>> from sklearn.metrics import accuracy_score
>>> y_pred = [0, 2, 1, 3]
>>> y_true = [0, 1, 2, 3]
>>> accuracy_score(y_true, y_pred)
0.5
>>> accuracy_score(y_true, y_pred, normalize=False)
2
```

In the multilabel case with binary label indicators:

```
>>> accuracy_score(np.array([[0, 1], [1, 1]]), np.ones((2, 2)))
0.5
```

### Example:

- See [Test with permutations the significance of a classification score](#) for an example of accuracy score usage using permutations of the dataset.

## Cohen's kappa

The function `cohen_kappa_score` computes Cohen's kappa statistic. This measure is intended to compare labelings by different human annotators, not a classifier versus a ground truth.

The kappa score (see docstring) is a number between -1 and 1. Scores above .8 are generally considered good agreement; zero or lower means no agreement (practically random labels).

Kappa scores can be computed for binary or multiclass problems, but not for multilabel problems (except by manually computing a per-label score) and not for more than two annotators.

```
>>> from sklearn.metrics import cohen_kappa_score
>>> y_true = [2, 0, 2, 2, 0, 1]
>>> y_pred = [0, 0, 2, 2, 0, 2]
>>> cohen_kappa_score(y_true, y_pred)
0.4285714285714286
```

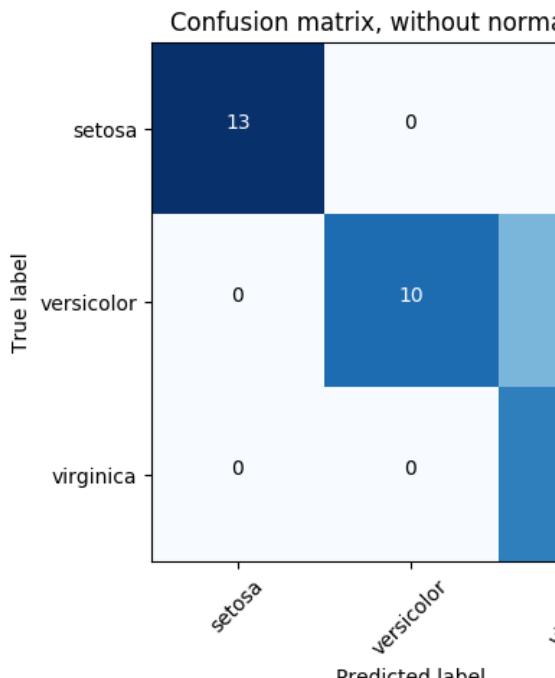

## Confusion matrix

The `confusion_matrix` function evaluates classification accuracy by computing the confusion matrix.

By definition, entry  $i, j$  in a confusion matrix is the number of observations actually in group  $i$ , but predicted to be in group  $j$ . Here is an example:

```
>>> from sklearn.metrics import confusion_matrix
>>> y_true = [2, 0, 2, 2, 0, 1]
>>> y_pred = [0, 0, 2, 2, 0, 2]
>>> confusion_matrix(y_true, y_pred)
array([[2, 0, 0],
       [0, 0, 1],
       [1, 0, 2]])
```

Here is a visual representation of such a confusion matrix (this figure comes from the [Confusion matrix](#) example):

For binary problems, we can

get counts of true negatives, false positives, false negatives and true positives as follows:

```
>>> y_true = [0, 0, 0, 1, 1, 1, 1]
>>> y_pred = [0, 1, 0, 1, 0, 1, 1]
>>> tn, fp, fn, tp = confusion_matrix(y_true, y_pred).ravel()
>>> tn, fp, fn, tp
(2, 1, 2, 3)
```

### Example:

- See [Confusion matrix](#) for an example of using a confusion matrix to evaluate classifier output quality.
- See [Recognizing hand-written digits](#) for an example of using a confusion matrix to classify hand-written digits.
- See [Classification of text documents using sparse features](#) for an example of using a confusion matrix to classify text documents.

## Classification report

The `classification_report` function builds a text report showing the main classification metrics. Here is a small example with custom `target_names` and inferred labels:

```
>>> from sklearn.metrics import classification_report
>>> y_true = [0, 1, 2, 2, 0]
>>> y_pred = [0, 0, 2, 1, 0]
>>> target_names = ['class 0', 'class 1', 'class 2']
>>> print(classification_report(y_true, y_pred, target_names=target_names))
      precision    recall  f1-score   support

  class 0       0.67     1.00     0.80      2
  class 1       0.00     0.00     0.00      1
  class 2       1.00     0.50     0.67      2

avg / total    0.67     0.60     0.59      5
```

**Example:**

- See [Recognizing hand-written digits](#) for an example of classification report usage for hand-written digits.
- See [Classification of text documents using sparse features](#) for an example of classification report usage for text documents.
- See [sphx\\_glr\\_auto\\_examples\\_model\\_selection\\_grid\\_search\\_digits.py](#) for an example of classification report usage for grid search with nested cross-validation.

## Hamming loss

The [hamming\\_loss](#) computes the average Hamming loss or [Hamming distance](#) between two sets of samples.

If  $\hat{y}_j$  is the predicted value for the  $j$ -th label of a given sample,  $y_j$  is the corresponding true value, and  $n_{\text{labels}}$  is the number of classes or labels, then the Hamming loss  $L_{\text{Hamming}}$  between two samples is defined as:

$$L_{\text{Hamming}}(y, \hat{y}) = \frac{1}{n_{\text{labels}}} \sum_{j=0}^{n_{\text{labels}}-1} 1(\hat{y}_j \neq y_j)$$

where  $1(x)$  is the indicator function.

```
>>> from sklearn.metrics import hamming_loss
>>> y_pred = [1, 2, 3, 4]
>>> y_true = [2, 2, 3, 4]
>>> hamming_loss(y_true, y_pred)
0.25
```

In the multilabel case with binary label indicators:

```
>>> hamming_loss(np.array([[0, 1], [1, 1]]), np.zeros((2, 2)))
0.75
```

---

**Note:** In multiclass classification, the Hamming loss corresponds to the Hamming distance between `y_true` and `y_pred` which is similar to the [Zero one loss](#) function. However, while zero-one loss penalizes prediction sets that do not strictly match true sets, the Hamming loss penalizes individual labels. Thus the Hamming loss, upper bounded by the zero-one loss, is always between zero and one, inclusive; and predicting a proper subset or superset of the true labels will give a Hamming loss between zero and one, exclusive.

---

## Jaccard similarity coefficient score

The `jaccard_similarity_score` function computes the average (default) or sum of Jaccard similarity coefficients, also called the Jaccard index, between pairs of label sets.

The Jaccard similarity coefficient of the  $i$ -th samples, with a ground truth label set  $y_i$  and predicted label set  $\hat{y}_i$ , is defined as

$$J(y_i, \hat{y}_i) = \frac{|y_i \cap \hat{y}_i|}{|y_i \cup \hat{y}_i|}.$$

In binary and multiclass classification, the Jaccard similarity coefficient score is equal to the classification accuracy.

```
>>> import numpy as np
>>> from sklearn.metrics import jaccard_similarity_score
>>> y_pred = [0, 2, 1, 3]
>>> y_true = [0, 1, 2, 3]
>>> jaccard_similarity_score(y_true, y_pred)
0.5
>>> jaccard_similarity_score(y_true, y_pred, normalize=False)
2
```

In the multilabel case with binary label indicators:

```
>>> jaccard_similarity_score(np.array([[0, 1], [1, 1]]), np.ones((2, 2)))
0.75
```

## Precision, recall and F-measures

Intuitively, `precision` is the ability of the classifier not to label as positive a sample that is negative, and `recall` is the ability of the classifier to find all the positive samples.

The  $F$ -measure ( $F_\beta$  and  $F_1$  measures) can be interpreted as a weighted harmonic mean of the precision and recall. A  $F_\beta$  measure reaches its best value at 1 and its worst score at 0. With  $\beta = 1$ ,  $F_\beta$  and  $F_1$  are equivalent, and the recall and the precision are equally important.

The `precision_recall_curve` computes a precision-recall curve from the ground truth label and a score given by the classifier by varying a decision threshold.

The `average_precision_score` function computes the average precision (AP) from prediction scores. This score corresponds to the area under the precision-recall curve. The value is between 0 and 1 and higher is better. With random predictions, the AP is the fraction of positive samples.

Several functions allow you to analyze the precision, recall and F-measures score:

<code>average_precision_score(y_true, y_score[, ...])</code>	Compute average precision (AP) from prediction scores
<code>f1_score(y_true, y_pred[, labels, ...])</code>	Compute the F1 score, also known as balanced F-score or F-measure
<code>fbeta_score(y_true, y_pred, beta[, labels, ...])</code>	Compute the F-beta score
<code>precision_recall_curve(y_true, probas_pred)</code>	Compute precision-recall pairs for different probability thresholds
<code>precision_recall_fscore_support(y_true, y_pred)</code>	Compute precision, recall, F-measure and support for each class
<code>precision_score(y_true, y_pred[, labels, ...])</code>	Compute the precision
<code>recall_score(y_true, y_pred[, labels, ...])</code>	Compute the recall

Note that the `precision_recall_curve` function is restricted to the binary case. The `average_precision_score` function works only in binary classification and multilabel indicator format.

### Examples:

- See [Classification of text documents using sparse features](#) for an example of `f1_score` usage to classify text documents.
- See [sphx\\_glr\\_auto\\_examples\\_model\\_selection\\_grid\\_search\\_digits.py](#) for an example of `precision_score` and `recall_score` usage to estimate parameters using grid search with nested cross-validation.
- See [Precision-Recall](#) for an example of `precision_recall_curve` usage to evaluate classifier output quality.
- See [Sparse recovery: feature selection for sparse linear models](#) for an example of `precision_recall_curve` usage to select features for sparse linear models.

## Binary classification

In a binary classification task, the terms “positive” and “negative” refer to the classifier’s prediction, and the terms “true” and “false” refer to whether that prediction corresponds to the external judgment (sometimes known as the “observation”). Given these definitions, we can formulate the following table:

	Actual class (observation)	
Predicted class (expectation)	tp (true positive) Correct result	fp (false positive) Unexpected result
	fn (false negative) Missing result	tn (true negative) Correct absence of result

In this context, we can define the notions of precision, recall and F-measure:

$$\text{precision} = \frac{tp}{tp + fp},$$

$$\text{recall} = \frac{tp}{tp + fn},$$

$$F_\beta = (1 + \beta^2) \frac{\text{precision} \times \text{recall}}{\beta^2 \text{precision} + \text{recall}}.$$

Here are some small examples in binary classification:

```
>>> from sklearn import metrics
>>> y_pred = [0, 1, 0, 0]
>>> y_true = [0, 1, 0, 1]
>>> metrics.precision_score(y_true, y_pred)
1.0
>>> metrics.recall_score(y_true, y_pred)
0.5
>>> metrics.f1_score(y_true, y_pred)
0.66...
>>> metrics.fbeta_score(y_true, y_pred, beta=0.5)
0.83...
>>> metrics.fbeta_score(y_true, y_pred, beta=1)
0.66...
>>> metrics.fbeta_score(y_true, y_pred, beta=2)
0.55...
>>> metrics.precision_recall_fscore_support(y_true, y_pred, beta=0.5)
```

```
(array([ 0.66..., 1.          ]), array([ 1. ,  0.5]), array([ 0.71...,  0.83...]),  
array([2, 2])))

>>> import numpy as np
>>> from sklearn.metrics import precision_recall_curve
>>> from sklearn.metrics import average_precision_score
>>> y_true = np.array([0, 0, 1, 1])
>>> y_scores = np.array([0.1, 0.4, 0.35, 0.8])
>>> precision, recall, threshold = precision_recall_curve(y_true, y_scores)
>>> precision
array([ 0.66...,  0.5       , 1.          , 1.          ])
>>> recall
array([ 1. ,  0.5,  0.5,  0. ])
>>> threshold
array([ 0.35,  0.4 ,  0.8 ])
>>> average_precision_score(y_true, y_scores)
0.79...
```

## Multiclass and multilabel classification

In multiclass and multilabel classification task, the notions of precision, recall, and F-measures can be applied to each label independently. There are a few ways to combine results across labels, specified by the `average` argument to the `average_precision_score` (multilabel only), `f1_score`, `fbeta_score`, `precision_recall_fscore_support`, `precision_score` and `recall_score` functions, as described [above](#). Note that for “micro”-averaging in a multiclass setting with all labels included will produce equal precision, recall and  $F$ , while “weighted” averaging may produce an F-score that is not between precision and recall.

To make this more explicit, consider the following notation:

- $y$  the set of *predicted (sample, label)* pairs
- $\hat{y}$  the set of *true (sample, label)* pairs
- $L$  the set of labels
- $S$  the set of samples
- $y_s$  the subset of  $y$  with sample  $s$ , i.e.  $y_s := \{(s', l) \in y | s' = s\}$
- $y_l$  the subset of  $y$  with label  $l$
- similarly,  $\hat{y}_s$  and  $\hat{y}_l$  are subsets of  $\hat{y}$
- $P(A, B) := \frac{|A \cap B|}{|A|}$
- $R(A, B) := \frac{|A \cap B|}{|B|}$  (Conventions vary on handling  $B = \emptyset$ ; this implementation uses  $R(A, B) := 0$ , and similar for  $P$ .)
- $F_\beta(A, B) := (1 + \beta^2) \frac{P(A, B) \times R(A, B)}{\beta^2 P(A, B) + R(A, B)}$

Then the metrics are defined as:

average	Precision	Recall	$F_\beta$
"micro"	$P(y, \hat{y})$	$R(y, \hat{y})$	$F_\beta(y, \hat{y})$
"samples"	$\frac{1}{ S } \sum_{s \in S} P(y_s, \hat{y}_s)$	$\frac{1}{ S } \sum_{s \in S} R(y_s, \hat{y}_s)$	$\frac{1}{ S } \sum_{s \in S} F_\beta(y_s, \hat{y}_s)$
"macro"	$\frac{1}{ L } \sum_{l \in L} P(y_l, \hat{y}_l)$	$\frac{1}{ L } \sum_{l \in L} R(y_l, \hat{y}_l)$	$\frac{1}{ L } \sum_{l \in L} F_\beta(y_l, \hat{y}_l)$
"weighted"	$\frac{1}{\sum_{l \in L}  \hat{y}_l } \sum_{l \in L}  \hat{y}_l  P(y_l, \hat{y}_l)$	$\frac{1}{\sum_{l \in L}  \hat{y}_l } \sum_{l \in L}  \hat{y}_l  R(y_l, \hat{y}_l)$	$\frac{1}{\sum_{l \in L}  \hat{y}_l } \sum_{l \in L}  \hat{y}_l  F_\beta(y_l, \hat{y}_l)$
None	$\langle P(y_l, \hat{y}_l)   l \in L \rangle$	$\langle R(y_l, \hat{y}_l)   l \in L \rangle$	$\langle F_\beta(y_l, \hat{y}_l)   l \in L \rangle$

```
>>> from sklearn import metrics
>>> y_true = [0, 1, 2, 0, 1, 2]
>>> y_pred = [0, 2, 1, 0, 0, 1]
>>> metrics.precision_score(y_true, y_pred, average='macro')
0.22...
>>> metrics.recall_score(y_true, y_pred, average='micro')
...
0.33...
>>> metrics.f1_score(y_true, y_pred, average='weighted')
0.26...
>>> metrics.fbeta_score(y_true, y_pred, average='macro', beta=0.5)
0.23...
>>> metrics.precision_recall_fscore_support(y_true, y_pred, beta=0.5, average=None)
...
(array([ 0.66...,  0.        ,  0.        ]), array([ 1.,  0.,  0.]), array([ 0.71...,  0.        ,  0.        ]), array([2, 2, 2]))
```

For multiclass classification with a “negative class”, it is possible to exclude some labels:

```
>>> metrics.recall_score(y_true, y_pred, labels=[1, 2], average='micro')
... # excluding 0, no labels were correctly recalled
0.0
```

Similarly, labels not present in the data sample may be accounted for in macro-averaging.

```
>>> metrics.precision_score(y_true, y_pred, labels=[0, 1, 2, 3], average='macro')
...
0.166...
```

## Hinge loss

The `hinge_loss` function computes the average distance between the model and the data using `hinge loss`, a one-sided metric that considers only prediction errors. (Hinge loss is used in maximal margin classifiers such as support vector machines.)

If the labels are encoded with +1 and -1,  $y$ : is the true value, and  $w$  is the predicted decisions as output by `decision_function`, then the hinge loss is defined as:

$$L_{\text{Hinge}}(y, w) = \max \{1 - wy, 0\} = |1 - wy|_+$$

If there are more than two labels, `hinge_loss` uses a multiclass variant due to Crammer & Singer. Here is the paper describing it.

If  $y_w$  is the predicted decision for true label and  $y_t$  is the maximum of the predicted decisions for all other labels, where predicted decisions are output by decision function, then multiclass hinge loss is defined by:

$$L_{\text{Hinge}}(y_w, y_t) = \max \{1 + y_t - y_w, 0\}$$

Here a small example demonstrating the use of the `hinge_loss` function with a svm classifier in a binary class problem:

```
>>> from sklearn import svm
>>> from sklearn.metrics import hinge_loss
>>> X = [[0], [1]]
>>> y = [-1, 1]
>>> est = svm.LinearSVC(random_state=0)
```

```
>>> est.fit(X, y)
LinearSVC(C=1.0, class_weight=None, dual=True, fit_intercept=True,
         intercept_scaling=1, loss='squared_hinge', max_iter=1000,
         multi_class='ovr', penalty='l2', random_state=0, tol=0.0001,
         verbose=0)
>>> pred_decision = est.decision_function([-2, 3, 0.5])
>>> pred_decision
array([-2.18..., 2.36..., 0.09...])
>>> hinge_loss([-1, 1, 1], pred_decision)
0.3...
```

Here is an example demonstrating the use of the `hinge_loss` function with a svm classifier in a multiclass problem:

```
>>> X = np.array([[0], [1], [2], [3]])
>>> Y = np.array([0, 1, 2, 3])
>>> labels = np.array([0, 1, 2, 3])
>>> est = svm.LinearSVC()
>>> est.fit(X, Y)
LinearSVC(C=1.0, class_weight=None, dual=True, fit_intercept=True,
         intercept_scaling=1, loss='squared_hinge', max_iter=1000,
         multi_class='ovr', penalty='l2', random_state=None, tol=0.0001,
         verbose=0)
>>> pred_decision = est.decision_function([-1, 2, 3])
>>> y_true = [0, 2, 3]
>>> hinge_loss(y_true, pred_decision, labels)
0.56...
```

## Log loss

Log loss, also called logistic regression loss or cross-entropy loss, is defined on probability estimates. It is commonly used in (multinomial) logistic regression and neural networks, as well as in some variants of expectation-maximization, and can be used to evaluate the probability outputs (`predict_proba`) of a classifier instead of its discrete predictions.

For binary classification with a true label  $y \in \{0, 1\}$  and a probability estimate  $p = \Pr(y=1)$ , the log loss per sample is the negative log-likelihood of the classifier given the true label:

$$L_{\log}(y, p) = -\log \Pr(y|p) = -(y \log(p) + (1-y) \log(1-p))$$

This extends to the multiclass case as follows. Let the true labels for a set of samples be encoded as a 1-of-K binary indicator matrix  $Y$ , i.e.,  $y_{i,k} = 1$  if sample  $i$  has label  $k$  taken from a set of  $K$  labels. Let  $P$  be a matrix of probability estimates, with  $p_{i,k} = \Pr(t_{i,k}=1)$ . Then the log loss of the whole set is

$$L_{\log}(Y, P) = -\log \Pr(Y|P) = -\frac{1}{N} \sum_{i=0}^{N-1} \sum_{k=0}^{K-1} y_{i,k} \log p_{i,k}$$

To see how this generalizes the binary log loss given above, note that in the binary case,  $p_{i,0} = 1 - p_{i,1}$  and  $y_{i,0} = 1 - y_{i,1}$ , so expanding the inner sum over  $y_{i,k} \in \{0, 1\}$  gives the binary log loss.

The `log_loss` function computes log loss given a list of ground-truth labels and a probability matrix, as returned by an estimator's `predict_proba` method.

```
>>> from sklearn.metrics import log_loss
>>> y_true = [0, 0, 1, 1]
>>> y_pred = [[.9, .1], [.8, .2], [.3, .7], [.01, .99]]
```

```
>>> log_loss(y_true, y_pred)
0.1738...
```

The first `[.9, .1]` in `y_pred` denotes 90% probability that the first sample has label 0. The log loss is non-negative.

### Matthews correlation coefficient

The `matthews_corrcoef` function computes the [Matthew's correlation coefficient \(MCC\)](#) for binary classes. Quoting Wikipedia:

“The Matthews correlation coefficient is used in machine learning as a measure of the quality of binary (two-class) classifications. It takes into account true and false positives and negatives and is generally regarded as a balanced measure which can be used even if the classes are of very different sizes. The MCC is in essence a correlation coefficient value between -1 and +1. A coefficient of +1 represents a perfect prediction, 0 an average random prediction and -1 an inverse prediction. The statistic is also known as the phi coefficient.”

If `tp`, `tn`, `fp` and `fn` are respectively the number of true positives, true negatives, false positives and false negatives, the MCC coefficient is defined as

$$MCC = \frac{tp \times tn - fp \times fn}{\sqrt{(tp + fp)(tp + fn)(tn + fp)(tn + fn)}}.$$

Here is a small example illustrating the usage of the `matthews_corrcoef` function:

```
>>> from sklearn.metrics import matthews_corrcoef
>>> y_true = [+1, +1, +1, -1]
>>> y_pred = [+1, -1, +1, +1]
>>> matthews_corrcoef(y_true, y_pred)
-0.33...
```

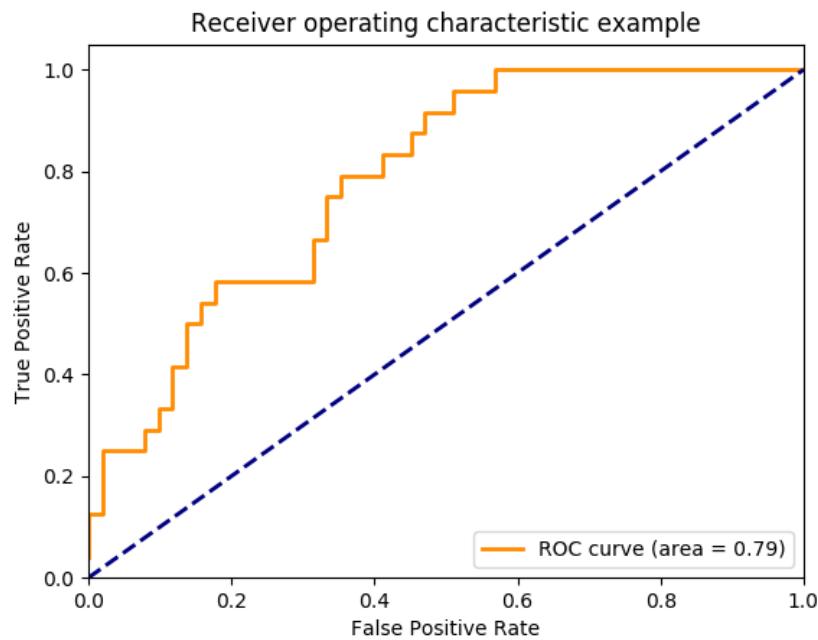

### Receiver operating characteristic (ROC)

The function `roc_curve` computes the [receiver operating characteristic curve](#), or ROC curve. Quoting Wikipedia :

“A receiver operating characteristic (ROC), or simply ROC curve, is a graphical plot which illustrates the performance of a binary classifier system as its discrimination threshold is varied. It is created by plotting the fraction of true positives out of the positives (TPR = true positive rate) vs. the fraction of false positives out of the negatives (FPR = false positive rate), at various threshold settings. TPR is also known as sensitivity, and FPR is one minus the specificity or true negative rate.”

This function requires the true binary value and the target scores, which can either be probability estimates of the positive class, confidence values, or binary decisions. Here is a small example of how to use the `roc_curve` function:

```
>>> import numpy as np
>>> from sklearn.metrics import roc_curve
>>> y = np.array([1, 1, 2, 2])
>>> scores = np.array([0.1, 0.4, 0.35, 0.8])
>>> fpr, tpr, thresholds = roc_curve(y, scores, pos_label=2)
>>> fpr
array([ 0.,  0.5,  0.5,  1. ])
>>> tpr
array([ 0.5,  0.5,  1.,  1. ])
>>> thresholds
array([ 0.8,  0.4,  0.35,  0.1])
```

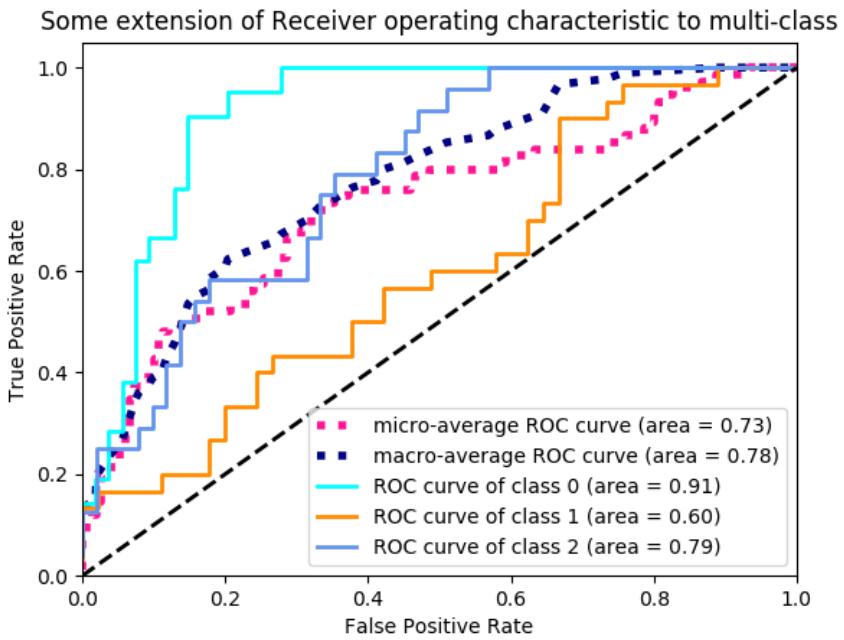

This figure shows an example of such an ROC curve:

The `roc_auc_score` function computes the area under the receiver operating characteristic (ROC) curve, which is also denoted by AUC or AUROC. By computing the area under the roc curve, the curve information is summarized in one number. For more information see the [Wikipedia article on AUC](#).

```
>>> import numpy as np
>>> from sklearn.metrics import roc_auc_score
>>> y_true = np.array([0, 0, 1, 1])
>>> y_scores = np.array([0.1, 0.4, 0.35, 0.8])
>>> roc_auc_score(y_true, y_scores)
0.75
```

In multi-label classification, the `roc_auc_score` function is extended by averaging over the labels as [above](#).

Compared to metrics such as the subset accuracy, the Hamming loss, or the F1 score, ROC doesn't require optimizing a threshold for each label. The `roc_auc_score` function can also be used in multi-class classification, if the predicted

outputs have been binarized.

#### Examples:

- See [Receiver Operating Characteristic \(ROC\)](#) for an example of using ROC to evaluate the quality of the output of a classifier.
- See [Receiver Operating Characteristic \(ROC\) with cross validation](#) for an example of using ROC to evaluate classifier output quality, using cross-validation.
- See [Species distribution modeling](#) for an example of using ROC to model species distribution.

## Zero one loss

The `zero_one_loss` function computes the sum or the average of the 0-1 classification loss ( $L_{0-1}$ ) over  $n_{\text{samples}}$ . By default, the function normalizes over the sample. To get the sum of the  $L_{0-1}$ , set `normalize` to `False`.

In multilabel classification, the `zero_one_loss` scores a subset as one if its labels strictly match the predictions, and as a zero if there are any errors. By default, the function returns the percentage of imperfectly predicted subsets. To get the count of such subsets instead, set `normalize` to `False`

If  $\hat{y}_i$  is the predicted value of the  $i$ -th sample and  $y_i$  is the corresponding true value, then the 0-1 loss  $L_{0-1}$  is defined as:

$$L_{0-1}(y_i, \hat{y}_i) = 1(\hat{y}_i \neq y_i)$$

where  $1(x)$  is the indicator function.

```
>>> from sklearn.metrics import zero_one_loss
>>> y_pred = [1, 2, 3, 4]
>>> y_true = [2, 2, 3, 4]
>>> zero_one_loss(y_true, y_pred)
0.25
```

```
>>> zero_one_loss(y_true, y_pred, normalize=False)
1
```

In the multilabel case with binary label indicators, where the first label set [0,1] has an error:

```
>>> zero_one_loss(np.array([[0, 1], [1, 1]]), np.ones((2, 2)))
0.5

>>> zero_one_loss(np.array([[0, 1], [1, 1]]), np.ones((2, 2)), normalize=False)
1
```

### Example:

- See [Recursive feature elimination with cross-validation](#) for an example of zero one loss usage to perform recursive feature elimination with cross-validation.

## Brier score loss

The `brier_score_loss` function computes the Brier score for binary classes. Quoting Wikipedia:

“The Brier score is a proper score function that measures the accuracy of probabilistic predictions. It is applicable to tasks in which predictions must assign probabilities to a set of mutually exclusive discrete outcomes.”

This function returns a score of the mean square difference between the actual outcome and the predicted probability of the possible outcome. The actual outcome has to be 1 or 0 (true or false), while the predicted probability of the actual outcome can be a value between 0 and 1.

The brier score loss is also between 0 to 1 and the lower the score (the mean square difference is smaller), the more accurate the prediction is. It can be thought of as a measure of the “calibration” of a set of probabilistic predictions.

$$BS = \frac{1}{N} \sum_{t=1}^N (f_t - o_t)^2$$

where :  $N$  is the total number of predictions,  $f_t$  is the predicted probability of the actual outcome  $o_t$ .

Here is a small example of usage of this function::

```
>>> import numpy as np
>>> from sklearn.metrics import brier_score_loss
>>> y_true = np.array([0, 1, 1, 0])
>>> y_true_categorical = np.array(["spam", "ham", "ham", "spam"])
>>> y_prob = np.array([0.1, 0.9, 0.8, 0.4])
>>> y_pred = np.array([0, 1, 1, 0])
>>> brier_score_loss(y_true, y_prob)
0.055
>>> brier_score_loss(y_true, 1-y_prob, pos_label=0)
0.055
>>> brier_score_loss(y_true_categorical, y_prob, pos_label="ham")
0.055
>>> brier_score_loss(y_true, y_prob > 0.5)
0.0
```

**Example:**

- See [Probability calibration of classifiers](#) for an example of Brier score loss usage to perform probability calibration of classifiers.

**References:**

- G. Brier, [Verification of forecasts expressed in terms of probability](#), Monthly weather review 78.1 (1950)

**Multilabel ranking metrics**

In multilabel learning, each sample can have any number of ground truth labels associated with it. The goal is to give high scores and better rank to the ground truth labels.

**Coverage error**

The [coverage\\_error](#) function computes the average number of labels that have to be included in the final prediction such that all true labels are predicted. This is useful if you want to know how many top-scored-labels you have to predict in average without missing any true one. The best value of this metric is thus the average number of true labels.

---

**Note:** Our implementation's score is 1 greater than the one given in Tsoumakas et al., 2010. This extends it to handle the degenerate case in which an instance has 0 true labels.

---

Formally, given a binary indicator matrix of the ground truth labels  $y \in \{0, 1\}^{n_{\text{samples}} \times n_{\text{labels}}}$  and the score associated with each label  $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$ , the coverage is defined as

$$\text{coverage}(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \max_{j:y_{ij}=1} \text{rank}_{ij}$$

with  $\text{rank}_{ij} = |\{k : \hat{f}_{ik} \geq \hat{f}_{ij}\}|$ . Given the rank definition, ties in `y_scores` are broken by giving the maximal rank that would have been assigned to all tied values.

Here is a small example of usage of this function:

```
>>> import numpy as np
>>> from sklearn.metrics import coverage_error
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> coverage_error(y_true, y_score)
2.5
```

**Label ranking average precision**

The [label\\_ranking\\_average\\_precision\\_score](#) function implements label ranking average precision (LRAP). This metric is linked to the [average\\_precision\\_score](#) function, but is based on the notion of label ranking instead of precision and recall.

Label ranking average precision (LRAP) is the average over each ground truth label assigned to each sample, of the ratio of true vs. total labels with lower score. This metric will yield better scores if you are able to give better rank to the labels associated with each sample. The obtained score is always strictly greater than 0, and the best value is 1. If there is exactly one relevant label per sample, label ranking average precision is equivalent to the [mean reciprocal rank](#).

Formally, given a binary indicator matrix of the ground truth labels  $y \in \mathcal{R}^{n_{\text{samples}} \times n_{\text{labels}}}$  and the score associated with each label  $\hat{f} \in \mathcal{R}^{n_{\text{samples}} \times n_{\text{labels}}}$ , the average precision is defined as

$$LRAP(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \frac{1}{|y_i|} \sum_{j:y_{ij}=1} \frac{|\mathcal{L}_{ij}|}{\text{rank}_{ij}}$$

with  $\mathcal{L}_{ij} = \left\{ k : y_{ik} = 1, \hat{f}_{ik} \geq \hat{f}_{ij} \right\}$ ,  $\text{rank}_{ij} = \left| \left\{ k : \hat{f}_{ik} \geq \hat{f}_{ij} \right\} \right|$  and  $|\cdot|$  is the  $\ell_0$  norm or the cardinality of the set.

Here is a small example of usage of this function:

```
>>> import numpy as np
>>> from sklearn.metrics import label_ranking_average_precision_score
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> label_ranking_average_precision_score(y_true, y_score)
0.416...
```

## Ranking loss

The [label\\_ranking\\_loss](#) function computes the ranking loss which averages over the samples the number of label pairs that are incorrectly ordered, i.e. true labels have a lower score than false labels, weighted by the inverse number of false and true labels. The lowest achievable ranking loss is zero.

Formally, given a binary indicator matrix of the ground truth labels  $y \in \{0, 1\}^{n_{\text{samples}} \times n_{\text{labels}}}$  and the score associated with each label  $\hat{f} \in \mathbb{R}^{n_{\text{samples}} \times n_{\text{labels}}}$ , the ranking loss is defined as

$$\text{ranking\_loss}(y, \hat{f}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} \frac{1}{|y_i|(n_{\text{labels}} - |y_i|)} \left| \left\{ (k, l) : \hat{f}_{ik} < \hat{f}_{il}, y_{ik} = 1, y_{il} = 0 \right\} \right|$$

where  $|\cdot|$  is the  $\ell_0$  norm or the cardinality of the set.

Here is a small example of usage of this function:

```
>>> import numpy as np
>>> from sklearn.metrics import label_ranking_loss
>>> y_true = np.array([[1, 0, 0], [0, 0, 1]])
>>> y_score = np.array([[0.75, 0.5, 1], [1, 0.2, 0.1]])
>>> label_ranking_loss(y_true, y_score)
0.75...
>>> # With the following prediction, we have perfect and minimal loss
>>> y_score = np.array([[1.0, 0.1, 0.2], [0.1, 0.2, 0.9]])
>>> label_ranking_loss(y_true, y_score)
0.0
```

## Regression metrics

The `sklearn.metrics` module implements several loss, score, and utility functions to measure regression performance. Some of those have been enhanced to handle the multioutput case: `mean_squared_error`, `mean_absolute_error`, `explained_variance_score` and `r2_score`.

These functions have an `multioutput` keyword argument which specifies the way the scores or losses for each individual target should be averaged. The default is `'uniform_average'`, which specifies a uniformly weighted mean over outputs. If an ndarray of shape `(n_outputs,)` is passed, then its entries are interpreted as weights and an according weighted average is returned. If `multioutput` is `'raw_values'` is specified, then all unaltered individual scores or losses will be returned in an array of shape `(n_outputs,)`.

The `r2_score` and `explained_variance_score` accept an additional value `'variance_weighted'` for the `multioutput` parameter. This option leads to a weighting of each individual score by the variance of the corresponding target variable. This setting quantifies the globally captured unscaled variance. If the target variables are of different scale, then this score puts more importance on well explaining the higher variance variables. `multioutput='variance_weighted'` is the default value for `r2_score` for backward compatibility. This will be changed to `uniform_average` in the future.

### Explained variance score

The `explained_variance_score` computes the explained variance regression score.

If  $\hat{y}$  is the estimated target output,  $y$  the corresponding (correct) target output, and  $Var$  is Variance, the square of the standard deviation, then the explained variance is estimated as follow:

$$\text{explained\_variance}(y, \hat{y}) = 1 - \frac{\text{Var}\{y - \hat{y}\}}{\text{Var}\{y\}}$$

The best possible score is 1.0, lower values are worse.

Here is a small example of usage of the `explained_variance_score` function:

```
>>> from sklearn.metrics import explained_variance_score
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> explained_variance_score(y_true, y_pred)
0.957...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> explained_variance_score(y_true, y_pred, multioutput='raw_values')
...
array([ 0.967...,  1.        ])
>>> explained_variance_score(y_true, y_pred, multioutput=[0.3, 0.7])
...
0.990...
```

### Mean absolute error

The `mean_absolute_error` function computes `mean absolute error`, a risk metric corresponding to the expected value of the absolute error loss or  $l1$ -norm loss.

If  $\hat{y}_i$  is the predicted value of the  $i$ -th sample, and  $y_i$  is the corresponding true value, then the mean absolute error (MAE) estimated over  $n_{\text{samples}}$  is defined as

$$\text{MAE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} |y_i - \hat{y}_i|.$$

Here is a small example of usage of the `mean_absolute_error` function:

```
>>> from sklearn.metrics import mean_absolute_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> mean_absolute_error(y_true, y_pred)
0.5
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> mean_absolute_error(y_true, y_pred)
0.75
>>> mean_absolute_error(y_true, y_pred, multioutput='raw_values')
array([ 0.5,  1. ])
>>> mean_absolute_error(y_true, y_pred, multioutput=[0.3, 0.7])
...
0.849...
```

## Mean squared error

The `mean_squared_error` function computes `mean square error`, a risk metric corresponding to the expected value of the squared (quadratic) error or loss.

If  $\hat{y}_i$  is the predicted value of the  $i$ -th sample, and  $y_i$  is the corresponding true value, then the mean squared error (MSE) estimated over  $n_{\text{samples}}$  is defined as

$$\text{MSE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (y_i - \hat{y}_i)^2.$$

Here is a small example of usage of the `mean_squared_error` function:

```
>>> from sklearn.metrics import mean_squared_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> mean_squared_error(y_true, y_pred)
0.375
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> mean_squared_error(y_true, y_pred)
0.7083...
```

### Examples:

- See [Gradient Boosting regression](#) for an example of mean squared error usage to evaluate gradient boosting regression.

## Mean squared logarithmic error

The `mean_squared_log_error` function computes a risk metric corresponding to the expected value of the squared logarithmic (quadratic) error or loss.

If  $\hat{y}_i$  is the predicted value of the  $i$ -th sample, and  $y_i$  is the corresponding true value, then the mean squared logarithmic

error (MSLE) estimated over  $n_{\text{samples}}$  is defined as

$$\text{MSLE}(y, \hat{y}) = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} (\log_e(1 + y_i) - \log_e(1 + \hat{y}_i))^2.$$

Where  $\log_e(x)$  means the natural logarithm of  $x$ . This metric is best to use when targets having exponential growth, such as population counts, average sales of a commodity over a span of years etc. Note that this metric penalizes an under-predicted estimate greater than an over-predicted estimate.

Here is a small example of usage of the `mean_squared_log_error` function:

```
>>> from sklearn.metrics import mean_squared_log_error
>>> y_true = [3, 5, 2.5, 7]
>>> y_pred = [2.5, 5, 4, 8]
>>> mean_squared_log_error(y_true, y_pred)
0.039...
>>> y_true = [[0.5, 1], [1, 2], [7, 6]]
>>> y_pred = [[0.5, 2], [1, 2.5], [8, 8]]
>>> mean_squared_log_error(y_true, y_pred)
0.044...
```

## Median absolute error

The `median_absolute_error` is particularly interesting because it is robust to outliers. The loss is calculated by taking the median of all absolute differences between the target and the prediction.

If  $\hat{y}_i$  is the predicted value of the  $i$ -th sample and  $y_i$  is the corresponding true value, then the median absolute error (MedAE) estimated over  $n_{\text{samples}}$  is defined as

$$\text{MedAE}(y, \hat{y}) = \text{median}(|y_1 - \hat{y}_1|, \dots, |y_n - \hat{y}_n|).$$

The `median_absolute_error` does not support multioutput.

Here is a small example of usage of the `median_absolute_error` function:

```
>>> from sklearn.metrics import median_absolute_error
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> median_absolute_error(y_true, y_pred)
0.5
```

## R<sup>2</sup> score, the coefficient of determination

The `r2_score` function computes R<sup>2</sup>, the coefficient of determination. It provides a measure of how well future samples are likely to be predicted by the model. Best possible score is 1.0 and it can be negative (because the model can be arbitrarily worse). A constant model that always predicts the expected value of y, disregarding the input features, would get a R<sup>2</sup> score of 0.0.

If  $\hat{y}_i$  is the predicted value of the  $i$ -th sample and  $y_i$  is the corresponding true value, then the score R<sup>2</sup> estimated over  $n_{\text{samples}}$  is defined as

$$R^2(y, \hat{y}) = 1 - \frac{\sum_{i=0}^{n_{\text{samples}}-1} (y_i - \hat{y}_i)^2}{\sum_{i=0}^{n_{\text{samples}}-1} (y_i - \bar{y})^2}$$

where  $\bar{y} = \frac{1}{n_{\text{samples}}} \sum_{i=0}^{n_{\text{samples}}-1} y_i$ .

Here is a small example of usage of the `r2_score` function:

```
>>> from sklearn.metrics import r2_score
>>> y_true = [3, -0.5, 2, 7]
>>> y_pred = [2.5, 0.0, 2, 8]
>>> r2_score(y_true, y_pred)
0.948...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> r2_score(y_true, y_pred, multioutput='variance_weighted')
...
0.938...
>>> y_true = [[0.5, 1], [-1, 1], [7, -6]]
>>> y_pred = [[0, 2], [-1, 2], [8, -5]]
>>> r2_score(y_true, y_pred, multioutput='uniform_average')
...
0.936...
>>> r2_score(y_true, y_pred, multioutput='raw_values')
...
array([ 0.965...,  0.908...])
>>> r2_score(y_true, y_pred, multioutput=[0.3, 0.7])
...
0.925...
```

### Example:

- See [Lasso and Elastic Net for Sparse Signals](#) for an example of R<sup>2</sup> score usage to evaluate Lasso and Elastic Net on sparse signals.

## Clustering metrics

The `sklearn.metrics` module implements several loss, score, and utility functions. For more information see the [Clustering performance evaluation](#) section for instance clustering, and [Biclustering evaluation](#) for biclustering.

## Dummy estimators

When doing supervised learning, a simple sanity check consists of comparing one's estimator against simple rules of thumb. `DummyClassifier` implements several such simple strategies for classification:

- `stratified` generates random predictions by respecting the training set class distribution.
- `most_frequent` always predicts the most frequent label in the training set.
- `prior` always predicts the class that maximizes the class prior (like `most_frequent`) and ```predict_proba` returns the class prior.
- `uniform` generates predictions uniformly at random.
- **`constant` always predicts a constant label that is provided by the user.** A major motivation of this method is F1-scoring, when the positive class is in the minority.

Note that with all these strategies, the `predict` method completely ignores the input data!

To illustrate `DummyClassifier`, first let's create an imbalanced dataset:

```
>>> from sklearn.datasets import load_iris
>>> from sklearn.model_selection import train_test_split
>>> iris = load_iris()
>>> X, y = iris.data, iris.target
>>> y[y != 1] = -1
>>> X_train, X_test, y_train, y_test = train_test_split(X, y, random_state=0)
```

Next, let's compare the accuracy of SVC and most\_frequent:

```
>>> from sklearn.dummy import DummyClassifier
>>> from sklearn.svm import SVC
>>> clf = SVC(kernel='linear', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.63...
>>> clf = DummyClassifier(strategy='most_frequent', random_state=0)
>>> clf.fit(X_train, y_train)
DummyClassifier(constant=None, random_state=0, strategy='most_frequent')
>>> clf.score(X_test, y_test)
0.57...
```

We see that SVC doesn't do much better than a dummy classifier. Now, let's change the kernel:

```
>>> clf = SVC(kernel='rbf', C=1).fit(X_train, y_train)
>>> clf.score(X_test, y_test)
0.97...
```

We see that the accuracy was boosted to almost 100%. A cross validation strategy is recommended for a better estimate of the accuracy, if it is not too CPU costly. For more information see the [Cross-validation: evaluating estimator performance](#) section. Moreover if you want to optimize over the parameter space, it is highly recommended to use an appropriate methodology; see the [Tuning the hyper-parameters of an estimator](#) section for details.

More generally, when the accuracy of a classifier is too close to random, it probably means that something went wrong: features are not helpful, a hyperparameter is not correctly tuned, the classifier is suffering from class imbalance, etc...

[DummyRegressor](#) also implements four simple rules of thumb for regression:

- mean always predicts the mean of the training targets.
- median always predicts the median of the training targets.
- quantile always predicts a user provided quantile of the training targets.
- constant always predicts a constant value that is provided by the user.

In all these strategies, the predict method completely ignores the input data.

### 3.3.4 Model persistence

After training a scikit-learn model, it is desirable to have a way to persist the model for future use without having to retrain. The following section gives you an example of how to persist a model with pickle. We'll also review a few security and maintainability issues when working with pickle serialization.

#### Persistence example

It is possible to save a model in the scikit by using Python's built-in persistence model, namely `pickle`:

```
>>> from sklearn import svm
>>> from sklearn import datasets
>>> clf = svm.SVC()
>>> iris = datasets.load_iris()
>>> X, y = iris.data, iris.target
>>> clf.fit(X, y)
SVC(C=1.0, cache_size=200, class_weight=None, coef0=0.0,
    decision_function_shape='ovr', degree=3, gamma='auto', kernel='rbf',
    max_iter=-1, probability=False, random_state=None, shrinking=True,
    tol=0.001, verbose=False)

>>> import pickle
>>> s = pickle.dumps(clf)
>>> clf2 = pickle.loads(s)
>>> clf2.predict(X[0:1])
array([0])
>>> y[0]
0
```

In the specific case of the scikit, it may be more interesting to use joblib's replacement of pickle (`joblib.dump` & `joblib.load`), which is more efficient on objects that carry large numpy arrays internally as is often the case for fitted scikit-learn estimators, but can only pickle to the disk and not to a string:

```
>>> from sklearn.externals import joblib
>>> joblib.dump(clf, 'filename.pkl')
```

Later you can load back the pickled model (possibly in another Python process) with:

```
>>> clf = joblib.load('filename.pkl')
```

---

**Note:** `joblib.dump` and `joblib.load` functions also accept file-like object instead of filenames. More information on data persistence with Joblib is available [here](#).

---

## Security & maintainability limitations

pickle (and joblib by extension), has some issues regarding maintainability and security. Because of this,

- Never unpickle untrusted data as it could lead to malicious code being executed upon loading.
- While models saved using one version of scikit-learn might load in other versions, this is entirely unsupported and inadvisable. It should also be kept in mind that operations performed on such data could give different and unexpected results.

In order to rebuild a similar model with future versions of scikit-learn, additional metadata should be saved along the pickled model:

- The training data, e.g. a reference to a immutable snapshot
- The python source code used to generate the model
- The versions of scikit-learn and its dependencies
- The cross validation score obtained on the training data

This should make it possible to check that the cross-validation score is in the same range as before.

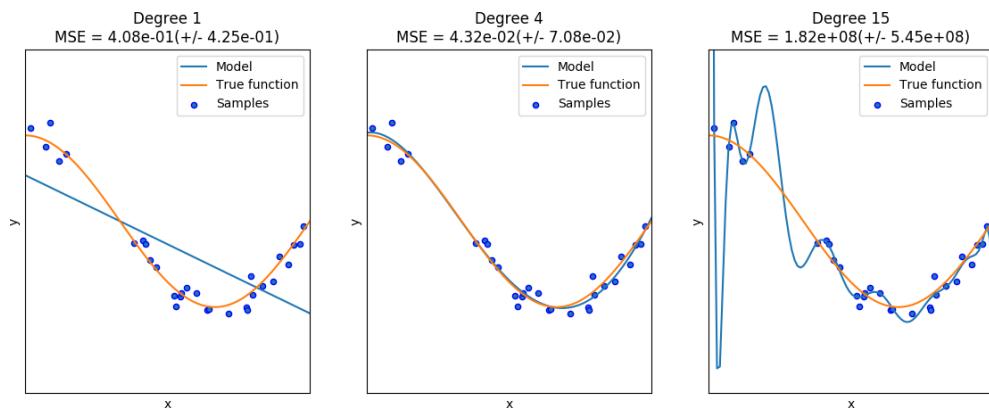

Since a model internal representation may be different on two different architectures, dumping a model on one architecture and loading it on another architecture is not supported.

If you want to know more about these issues and explore other possible serialization methods, please refer to this [talk by Alex Gaynor](#).

### 3.3.5 Validation curves: plotting scores to evaluate models

Every estimator has its advantages and drawbacks. Its generalization error can be decomposed in terms of bias, variance and noise. The **bias** of an estimator is its average error for different training sets. The **variance** of an estimator indicates how sensitive it is to varying training sets. Noise is a property of the data.

In the following plot, we see a function  $f(x) = \cos(\frac{3}{2}\pi x)$  and some noisy samples from that function. We use three different estimators to fit the function: linear regression with polynomial features of degree 1, 4 and 15. We see that the first estimator can at best provide only a poor fit to the samples and the true function because it is too simple (high bias), the second estimator approximates it almost perfectly and the last estimator approximates the training data perfectly but does not fit the true function very well, i.e. it is very sensitive to varying training data (high variance).

Bias and variance are inherent properties of estimators and we usually have to select learning algorithms and hyperparameters so that both bias and variance are as low as possible (see [Bias-variance dilemma](#)). Another way to reduce the variance of a model is to use more training data. However, you should only collect more training data if the true function is too complex to be approximated by an estimator with a lower variance.

In the simple one-dimensional problem that we have seen in the example it is easy to see whether the estimator suffers from bias or variance. However, in high-dimensional spaces, models can become very difficult to visualize. For this reason, it is often helpful to use the tools described below.

#### Examples:

- [Underfitting vs. Overfitting](#)
- [Plotting Validation Curves](#)
- [Plotting Learning Curves](#)

## Validation curve

To validate a model we need a scoring function (see [Model evaluation: quantifying the quality of predictions](#)), for example accuracy for classifiers. The proper way of choosing multiple hyperparameters of an estimator are of course grid search or similar methods (see [Tuning the hyper-parameters of an estimator](#)) that select the hyperparameter with the maximum score on a validation set or multiple validation sets. Note that if we optimized the hyperparameters based on a validation score the validation score is biased and not a good estimate of the generalization any longer. To get a proper estimate of the generalization we have to compute the score on another test set.

However, it is sometimes helpful to plot the influence of a single hyperparameter on the training score and the validation score to find out whether the estimator is overfitting or underfitting for some hyperparameter values.

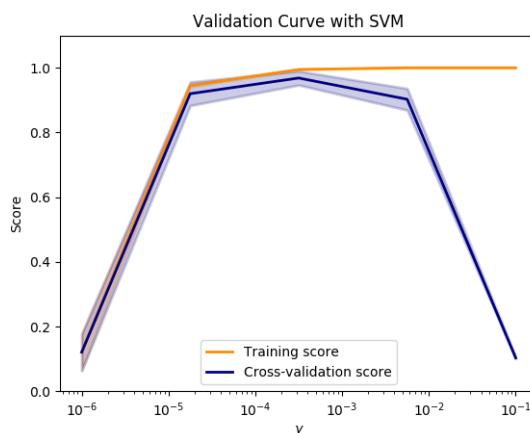

The function `validation_curve` can help in this case:

```
>>> import numpy as np
>>> from sklearn.model_selection import validation_curve
>>> from sklearn.datasets import load_iris
>>> from sklearn.linear_model import Ridge

>>> np.random.seed(0)
>>> iris = load_iris()
>>> X, y = iris.data, iris.target
>>> indices = np.arange(y.shape[0])
>>> np.random.shuffle(indices)
>>> X, y = X[indices], y[indices]

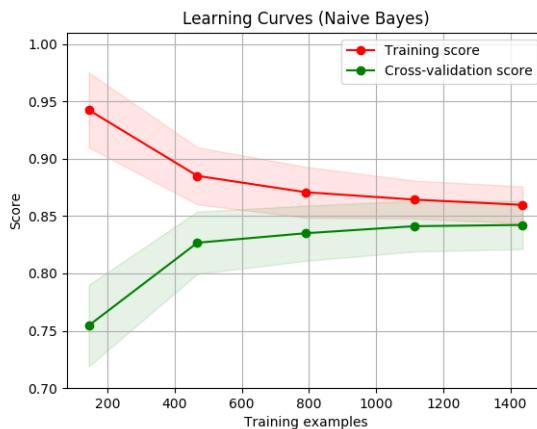

>>> train_scores, valid_scores = validation_curve(Ridge(), X, y, "alpha",
...                                               np.logspace(-7, 3, 3))
>>> train_scores
array([[ 0.94...,  0.92...,  0.92...],
       [ 0.94...,  0.92...,  0.92...],
       [ 0.47...,  0.45...,  0.42...]])
>>> valid_scores
array([[ 0.90...,  0.92...,  0.94...],
       [ 0.90...,  0.92...,  0.94...],
       [ 0.44...,  0.39...,  0.45...]])
```

If the training score and the validation score are both low, the estimator will be underfitting. If the training score is high and the validation score is low, the estimator is overfitting and otherwise it is working very well. A low training score and a high validation score is usually not possible. All three cases can be found in the plot below where we vary the parameter  $\gamma$  of an SVM on the digits dataset.

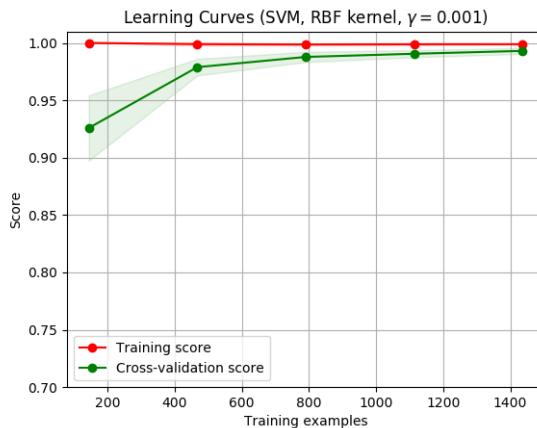

## Learning curve

A learning curve shows the validation and training score of an estimator for varying numbers of training samples. It is a tool to find out how much we benefit from adding more training data and whether the estimator suffers more from a variance error or a bias error. If both the validation score and the training score converge to a value that is too low with increasing size of the training set, we will not benefit much from more training data. In the following plot you can see an example: naive Bayes roughly converges to a low score.

We will probably have to use an estimator or a parametrization of the current estimator that can learn more complex concepts (i.e. has a lower bias). If the training score is much greater than the validation score for the maximum number of training samples, adding more training samples will most likely increase generalization. In the following plot you can see that the SVM could benefit from more training examples.

We can use the function `learning_curve` to generate the values that are required to plot such a learning curve (number of samples that have been used, the average scores on the training sets and the average scores on the validation sets):

```
>>> from sklearn.model_selection import learning_curve
>>> from sklearn.svm import SVC

>>> train_sizes, train_scores, valid_scores = learning_curve(
...     SVC(kernel='linear'), X, y, train_sizes=[50, 80, 110], cv=5)
>>> train_sizes
```

```
array([ 50,  80, 110])
>>> train_scores
array([[ 0.98...,  0.98 ,  0.98...,  0.98...,  0.98...],
       [ 0.98...,  1. ,  0.98...,  0.98...,  0.98...],
       [ 0.98...,  1. ,  0.98...,  0.98...,  0.99...]])
>>> valid_scores
array([[ 1. ,  0.93...,  1. ,  1. ,  0.96...],
       [ 1. ,  0.96...,  1. ,  1. ,  0.96...],
       [ 1. ,  0.96...,  1. ,  1. ,  0.96...]])
```

## 3.4 Dataset transformations

scikit-learn provides a library of transformers, which may clean (see [Preprocessing data](#)), reduce (see [Unsupervised dimensionality reduction](#)), expand (see [Kernel Approximation](#)) or generate (see [Feature extraction](#)) feature representations.

Like other estimators, these are represented by classes with a `fit` method, which learns model parameters (e.g. mean and standard deviation for normalization) from a training set, and a `transform` method which applies this transformation model to unseen data. `fit_transform` may be more convenient and efficient for modelling and transforming the training data simultaneously.

Combining such transformers, either in parallel or series is covered in [Pipeline and FeatureUnion: combining estimators](#). [Pairwise metrics, Affinities and Kernels](#) covers transforming feature spaces into affinity matrices, while [Transforming the prediction target \(`y`\)](#) considers transformations of the target space (e.g. categorical labels) for use in scikit-learn.

### 3.4.1 Pipeline and FeatureUnion: combining estimators

#### Pipeline: chaining estimators

[Pipeline](#) can be used to chain multiple estimators into one. This is useful as there is often a fixed sequence of steps in processing the data, for example feature selection, normalization and classification. [Pipeline](#) serves two purposes here:

**Convenience:** You only have to call `fit` and `predict` once on your data to fit a whole sequence of estimators.

**Joint parameter selection:** You can [grid search](#) over parameters of all estimators in the pipeline at once.

All estimators in a pipeline, except the last one, must be transformers (i.e. must have a `transform` method). The last estimator may be any type (transformer, classifier, etc.).

#### Usage

The [Pipeline](#) is built using a list of `(key, value)` pairs, where the key is a string containing the name you want to give this step and value is an estimator object:

```
>>> from sklearn.pipeline import Pipeline
>>> from sklearn.svm import SVC
>>> from sklearn.decomposition import PCA
>>> estimators = [('reduce_dim', PCA()), ('clf', SVC())]
>>> pipe = Pipeline(estimators)
>>> pipe
```

```
Pipeline(memory=None,
         steps=[('reduce_dim', PCA(copy=True, ...)),
                ('clf', SVC(C=1.0, ...))])
```

The utility function `make_pipeline` is a shorthand for constructing pipelines; it takes a variable number of estimators and returns a pipeline, filling in the names automatically:

```
>>> from sklearn.pipeline import make_pipeline
>>> from sklearn.naive_bayes import MultinomialNB
>>> from sklearn.preprocessing import Binarizer
>>> make_pipeline(Binarizer(), MultinomialNB())
Pipeline(memory=None,
         steps=[('binarizer', Binarizer(copy=True, threshold=0.0)),
                ('multinomialnb', MultinomialNB(alpha=1.0,
                                                class_prior=None,
                                                fit_prior=True))])
```

The estimators of a pipeline are stored as a list in the `steps` attribute:

```
>>> pipe.steps[0]
('reduce_dim', PCA(copy=True, iterated_power='auto', n_components=None, random_
                     state=None,
                     svd_solver='auto', tol=0.0, whiten=False))
```

and as a dict in `named_steps`:

```
>>> pipe.named_steps['reduce_dim']
PCA(copy=True, iterated_power='auto', n_components=None, random_state=None,
     svd_solver='auto', tol=0.0, whiten=False)
```

Parameters of the estimators in the pipeline can be accessed using the `<estimator>__<parameter>` syntax:

```
>>> pipe.set_params(clf__C=10)
Pipeline(memory=None,
         steps=[('reduce_dim', PCA(copy=True, iterated_power='auto', ...)),
                ('clf', SVC(C=10, cache_size=200, class_weight=None, ...))])
```

Attributes of `named_steps` map to keys, enabling tab completion in interactive environments:

```
>>> pipe.named_steps.reduce_dim is pipe.named_steps['reduce_dim']
True
```

This is particularly important for doing grid searches:

```
>>> from sklearn.model_selection import GridSearchCV
>>> param_grid = dict(reduce_dim__n_components=[2, 5, 10],
...                      clf__C=[0.1, 10, 100])
>>> grid_search = GridSearchCV(pipe, param_grid=param_grid)
```

Individual steps may also be replaced as parameters, and non-final steps may be ignored by setting them to `None`:

```
>>> from sklearn.linear_model import LogisticRegression
>>> param_grid = dict(reduce_dim=[None, PCA(5), PCA(10)],
...                      clf=[SVC(), LogisticRegression()],
...                      clf__C=[0.1, 10, 100])
>>> grid_search = GridSearchCV(pipe, param_grid=param_grid)
```

**Examples:**

- *Explicit feature map approximation for RBF kernels*
- *SVM-Anova: SVM with univariate feature selection*
- *Selecting dimensionality reduction with Pipeline and GridSearchCV*

**See also:**

- *Tuning the hyper-parameters of an estimator*

**Notes**

Calling `fit` on the pipeline is the same as calling `fit` on each estimator in turn, `transform` the input and pass it on to the next step. The pipeline has all the methods that the last estimator in the pipeline has, i.e. if the last estimator is a classifier, the `Pipeline` can be used as a classifier. If the last estimator is a transformer, again, so is the pipeline.

**Caching transformers: avoid repeated computation**

Fitting transformers may be computationally expensive. With its `memory` parameter set, `Pipeline` will cache each transformer after calling `fit`. This feature is used to avoid computing the fit transformers within a pipeline if the parameters and input data are identical. A typical example is the case of a grid search in which the transformers can be fitted only once and reused for each configuration.

The parameter `memory` is needed in order to cache the transformers. `memory` can be either a string containing the directory where to cache the transformers or a `joblib.Memory` object:

```
>>> from tempfile import mkdtemp
>>> from shutil import rmtree
>>> from sklearn.decomposition import PCA
>>> from sklearn.svm import SVC
>>> from sklearn.pipeline import Pipeline
>>> estimators = [('reduce_dim', PCA()), ('clf', SVC())]
>>> cachedir = mkdtemp()
>>> pipe = Pipeline(estimators, memory=cachedir)
>>> pipe
Pipeline(...,
          steps=[('reduce_dim', PCA(copy=True, ...)),
                 ('clf', SVC(C=1.0, ...))])
>>> # Clear the cache directory when you don't need it anymore
>>> rmtree(cachedir)
```

**Warning: Side effect of caching transfromers**

Using a `Pipeline` without cache enabled, it is possible to inspect the original instance such as:

```
>>> from sklearn.datasets import load_digits
>>> digits = load_digits()
>>> pca1 = PCA()
>>> svm1 = SVC()
>>> pipe = Pipeline([('reduce_dim', pca1), ('clf', svm1)])
>>> pipe.fit(digits.data, digits.target)
...
Pipeline(memory=None,
         steps=[('reduce_dim', PCA(...)), ('clf', SVC(...))])
>>> # The pca instance can be inspected directly
>>> print(pca1.components_)
[[ -1.77484909e-19 ... 4.07058917e-18]]
```

Enabling caching triggers a clone of the transformers before fitting. Therefore, the transformer instance given to the pipeline cannot be inspected directly. In following example, accessing the `PCA` instance `pca2` will raise an `AttributeError` since `pca2` will be an unfitted transformer. Instead, use the attribute `named_steps` to inspect estimators within the pipeline:

```
>>> cachedir = mkdtemp()
>>> pca2 = PCA()
>>> svm2 = SVC()
>>> cached_pipe = Pipeline([('reduce_dim', pca2), ('clf', svm2)],
...                         memory=cachedir)
>>> cached_pipe.fit(digits.data, digits.target)
...
Pipeline(memory=...,
         steps=[('reduce_dim', PCA(...)), ('clf', SVC(...))])
>>> print(cached_pipe.named_steps['reduce_dim'].components_)
...
[[ -1.77484909e-19 ... 4.07058917e-18]]
>>> # Remove the cache directory
>>> rmtree(cachedir)
```

## Examples:

- Selecting dimensionality reduction with `Pipeline` and `GridSearchCV`

## FeatureUnion: composite feature spaces

`FeatureUnion` combines several transformer objects into a new transformer that combines their output. A `FeatureUnion` takes a list of transformer objects. During fitting, each of these is fit to the data independently. For transforming data, the transformers are applied in parallel, and the sample vectors they output are concatenated end-to-end into larger vectors.

`FeatureUnion` serves the same purposes as `Pipeline` - convenience and joint parameter estimation and validation.

`FeatureUnion` and `Pipeline` can be combined to create complex models.

(A `FeatureUnion` has no way of checking whether two transformers might produce identical features. It only produces a union when the feature sets are disjoint, and making sure they are the caller's responsibility.)

## Usage

A `FeatureUnion` is built using a list of (key, value) pairs, where the key is the name you want to give to a given transformation (an arbitrary string; it only serves as an identifier) and value is an estimator object:

```
>>> from sklearn.pipeline import FeatureUnion
>>> from sklearn.decomposition import PCA
>>> from sklearn.decomposition import KernelPCA
>>> estimators = [('linear_pca', PCA()), ('kernel_pca', KernelPCA())]
>>> combined = FeatureUnion(estimators)
>>> combined
FeatureUnion(n_jobs=1,
             transformer_list=[('linear_pca', PCA(copy=True, ...)),
                               ('kernel_pca', KernelPCA(alpha=1.0, ...))],
             transformer_weights=None)
```

Like pipelines, feature unions have a shorthand constructor called `make_union` that does not require explicit naming of the components.

Like Pipeline, individual steps may be replaced using `set_params`, and ignored by setting to None:

```
>>> combined.set_params(kernel_pca=None)
...
FeatureUnion(n_jobs=1,
             transformer_list=[('linear_pca', PCA(copy=True, ...)),
                               ('kernel_pca', None)],
             transformer_weights=None)
```

### Examples:

## 3.4.2 Feature extraction

The `sklearn.feature_extraction` module can be used to extract features in a format supported by machine learning algorithms from datasets consisting of formats such as text and image.

---

**Note:** Feature extraction is very different from `Feature selection`: the former consists in transforming arbitrary data, such as text or images, into numerical features usable for machine learning. The latter is a machine learning technique applied on these features.

---

### Loading features from dicts

The class `DictVectorizer` can be used to convert feature arrays represented as lists of standard Python dict objects to the NumPy/SciPy representation used by scikit-learn estimators.

While not particularly fast to process, Python's dict has the advantages of being convenient to use, being sparse (absent features need not be stored) and storing feature names in addition to values.

`DictVectorizer` implements what is called one-of-K or “one-hot” coding for categorical (aka nominal, discrete) features. Categorical features are “attribute-value” pairs where the value is restricted to a list of discrete of possibilities without ordering (e.g. topic identifiers, types of objects, tags, names...).

In the following, “city” is a categorical attribute while “temperature” is a traditional numerical feature:

```
>>> measurements = [
...     {'city': 'Dubai', 'temperature': 33.},
...     {'city': 'London', 'temperature': 12.},
...     {'city': 'San Francisco', 'temperature': 18.},
... ]

>>> from sklearn.feature_extraction import DictVectorizer
>>> vec = DictVectorizer()

>>> vec.fit_transform(measurements).toarray()
array([[ 1.,  0.,  0.,  33.],
       [ 0.,  1.,  0.,  12.],
       [ 0.,  0.,  1.,  18.]])
```

```
>>> vec.get_feature_names()
['city=Dubai', 'city=London', 'city=San Francisco', 'temperature']
```

`DictVectorizer` is also a useful representation transformation for training sequence classifiers in Natural Language Processing models that typically work by extracting feature windows around a particular word of interest.

For example, suppose that we have a first algorithm that extracts Part of Speech (PoS) tags that we want to use as complementary tags for training a sequence classifier (e.g. a chunker). The following dict could be such a window of features extracted around the word ‘sat’ in the sentence ‘The cat sat on the mat.’:

```
>>> pos_window = [
...     {
...         'word-2': 'the',
...         'pos-2': 'DT',
...         'word-1': 'cat',
...         'pos-1': 'NN',
...         'word+1': 'on',
...         'pos+1': 'PP',
...     },
...     # in a real application one would extract many such dictionaries
... ]
```

This description can be vectorized into a sparse two-dimensional matrix suitable for feeding into a classifier (maybe after being piped into a `text.TfidfTransformer` for normalization):

```
>>> vec = DictVectorizer()
>>> pos_vectorized = vec.fit_transform(pos_window)
>>> pos_vectorized
<1x6 sparse matrix of type '<... 'numpy.float64'>'>
    with 6 stored elements in Compressed Sparse ... format>
>>> pos_vectorized.toarray()
array([[ 1.,  1.,  1.,  1.,  1.]])
>>> vec.get_feature_names()
['pos+1=PP', 'pos-1=NN', 'pos-2=DT', 'word+1=on', 'word-1=cat', 'word-2=the']
```

As you can imagine, if one extracts such a context around each individual word of a corpus of documents the resulting matrix will be very wide (many one-hot-features) with most of them being valued to zero most of the time. So as to make the resulting data structure able to fit in memory the `DictVectorizer` class uses a `scipy.sparse` matrix by default instead of a `numpy.ndarray`.

## Feature hashing

The class `FeatureHasher` is a high-speed, low-memory vectorizer that uses a technique known as [feature hashing](#), or the “hashing trick”. Instead of building a hash table of the features encountered in training, as the vectorizers do, instances of `FeatureHasher` apply a hash function to the features to determine their column index in sample matrices directly. The result is increased speed and reduced memory usage, at the expense of inspectability; the hasher does not remember what the input features looked like and has no `inverse_transform` method.

Since the hash function might cause collisions between (unrelated) features, a signed hash function is used and the sign of the hash value determines the sign of the value stored in the output matrix for a feature. This way, collisions are likely to cancel out rather than accumulate error, and the expected mean of any output feature’s value is zero.

If `non_negative=True` is passed to the constructor, the absolute value is taken. This undoes some of the collision handling, but allows the output to be passed to estimators like `sklearn.naive_bayes.MultinomialNB` or `sklearn.feature_selection.chi2` feature selectors that expect non-negative inputs.

`FeatureHasher` accepts either mappings (like Python’s `dict` and its variants in the `collections` module), `(feature, value)` pairs, or strings, depending on the constructor parameter `input_type`. Mappings are treated as lists of `(feature, value)` pairs, while single strings have an implicit value of 1, so `['feat1', 'feat2', 'feat3']` is interpreted as `[('feat1', 1), ('feat2', 1), ('feat3', 1)]`. If a single feature occurs multiple times in a sample, the associated values will be summed (so `('feat', 2)` and `('feat', 3.5)` become `('feat', 5.5)`). The output from `FeatureHasher` is always a `scipy.sparse` matrix in the CSR format.

Feature hashing can be employed in document classification, but unlike `text.CountVectorizer`, `FeatureHasher` does not do word splitting or any other preprocessing except Unicode-to-UTF-8 encoding; see [Vectorizing a large text corpus with the hashing trick](#), below, for a combined tokenizer/hasher.

As an example, consider a word-level natural language processing task that needs features extracted from `(token, part_of_speech)` pairs. One could use a Python generator function to extract features:

```
def token_features(token, part_of_speech):
    if token.isdigit():
        yield "numeric"
    else:
        yield "token={}".format(token.lower())
        yield "token,pos={},{}".format(token, part_of_speech)
    if token[0].isupper():
        yield "uppercase_initial"
    if token.isupper():
        yield "all_uppercase"
    yield "pos={}".format(part_of_speech)
```

Then, the `raw_X` to be fed to `FeatureHasher.transform` can be constructed using:

```
raw_X = (token_features(tok, pos_tagger(tok)) for tok in corpus)
```

and fed to a hasher with:

```
hasher = FeatureHasher(input_type='string')
X = hasher.transform(raw_X)
```

to get a `scipy.sparse` matrix `X`.

Note the use of a generator comprehension, which introduces laziness into the feature extraction: tokens are only processed on demand from the hasher.

## Implementation details

`FeatureHasher` uses the signed 32-bit variant of MurmurHash3. As a result (and because of limitations in `scipy.sparse`), the maximum number of features supported is currently  $2^{31} - 1$ .

The original formulation of the hashing trick by Weinberger et al. used two separate hash functions  $h$  and  $\xi$  to determine the column index and sign of a feature, respectively. The present implementation works under the assumption that the sign bit of MurmurHash3 is independent of its other bits.

Since a simple modulo is used to transform the hash function to a column index, it is advisable to use a power of two as the `n_features` parameter; otherwise the features will not be mapped evenly to the columns.

## Text feature extraction

### The Bag of Words representation

Text Analysis is a major application field for machine learning algorithms. However the raw data, a sequence of symbols cannot be fed directly to the algorithms themselves as most of them expect numerical feature vectors with a fixed size rather than the raw text documents with variable length.

In order to address this, scikit-learn provides utilities for the most common ways to extract numerical features from text content, namely:

- **tokenizing** strings and giving an integer id for each possible token, for instance by using white-spaces and punctuation as token separators.
- **counting** the occurrences of tokens in each document.
- **normalizing** and weighting with diminishing importance tokens that occur in the majority of samples / documents.

In this scheme, features and samples are defined as follows:

- each **individual token occurrence frequency** (normalized or not) is treated as a **feature**.
- the vector of all the token frequencies for a given **document** is considered a multivariate **sample**.

A corpus of documents can thus be represented by a matrix with one row per document and one column per token (e.g. word) occurring in the corpus.

We call **vectorization** the general process of turning a collection of text documents into numerical feature vectors. This specific strategy (tokenization, counting and normalization) is called the **Bag of Words** or “Bag of n-grams” representation. Documents are described by word occurrences while completely ignoring the relative position information of the words in the document.

## Sparsity

As most documents will typically use a very small subset of the words used in the corpus, the resulting matrix will have many feature values that are zeros (typically more than 99% of them).

For instance a collection of 10,000 short text documents (such as emails) will use a vocabulary with a size in the order of 100,000 unique words in total while each document will use 100 to 1000 unique words individually.

In order to be able to store such a matrix in memory but also to speed up algebraic operations matrix / vector, implementations will typically use a sparse representation such as the implementations available in the `scipy.sparse` package.

## Common Vectorizer usage

`CountVectorizer` implements both tokenization and occurrence counting in a single class:

```
>>> from sklearn.feature_extraction.text import CountVectorizer
```

This model has many parameters, however the default values are quite reasonable (please see the [reference documentation](#) for the details):

```
>>> vectorizer = CountVectorizer(min_df=1)
>>> vectorizer
CountVectorizer(analyzer='word', binary=False, decode_error='strict',
                dtype=<... 'numpy.int64'>, encoding='utf-8', input='content',
                lowercase=True, max_df=1.0, max_features=None, min_df=1,
                ngram_range=(1, 1), preprocessor=None, stop_words=None,
                strip_accents=None, token_pattern='(?u)\\b\\w+\\b',
                tokenizer=None, vocabulary=None)
```

Let's use it to tokenize and count the word occurrences of a minimalistic corpus of text documents:

```
>>> corpus = [
...     'This is the first document.',
...     'This is the second second document.',
...     'And the third one.',
...     'Is this the first document?',
... ]
>>> X = vectorizer.fit_transform(corpus)
>>> X
<4x9 sparse matrix of type '<... 'numpy.int64'>'>
    with 19 stored elements in Compressed Sparse ... format>
```

The default configuration tokenizes the string by extracting words of at least 2 letters. The specific function that does this step can be requested explicitly:

```
>>> analyze = vectorizer.build_analyzer()
>>> analyze("This is a text document to analyze.") == (
...     ['this', 'is', 'text', 'document', 'to', 'analyze'])
True
```

Each term found by the analyzer during the fit is assigned a unique integer index corresponding to a column in the resulting matrix. This interpretation of the columns can be retrieved as follows:

```
>>> vectorizer.get_feature_names() == (
...     ['and', 'document', 'first', 'is', 'one',
...      'second', 'the', 'third', 'this'])
True

>>> X.toarray()
array([[0, 1, 1, 1, 0, 0, 1, 0, 1],
       [0, 1, 0, 1, 0, 2, 1, 0, 1],
```

```
[1, 0, 0, 0, 1, 0, 1, 1, 0],
[0, 1, 1, 0, 0, 1, 0, 1]...)
```

The converse mapping from feature name to column index is stored in the `vocabulary_` attribute of the vectorizer:

```
>>> vectorizer.vocabulary_.get('document')
1
```

Hence words that were not seen in the training corpus will be completely ignored in future calls to the `transform` method:

```
>>> vectorizer.transform(['Something completely new.']).toarray()
...
array([[0, 0, 0, 0, 0, 0, 0, 0, 0]])...
```

Note that in the previous corpus, the first and the last documents have exactly the same words hence are encoded in equal vectors. In particular we lose the information that the last document is an interrogative form. To preserve some of the local ordering information we can extract 2-grams of words in addition to the 1-grams (individual words):

```
>>> bigram_vectorizer = CountVectorizer(ngram_range=(1, 2),
...                                         token_pattern=r'\b\w+\b', min_df=1)
>>> analyze = bigram_vectorizer.build_analyzer()
>>> analyze('Bi-grams are cool!') == (
...     ['bi', 'grams', 'are', 'cool', 'bi grams', 'grams are', 'are cool'])
True
```

The vocabulary extracted by this vectorizer is hence much bigger and can now resolve ambiguities encoded in local positioning patterns:

```
>>> X_2 = bigram_vectorizer.fit_transform(corpus).toarray()
>>> X_2
...
array([[0, 0, 1, 1, 1, 1, 0, 0, 0, 0, 0, 1, 1, 0, 0, 0, 0, 0, 1, 1, 0],
       [0, 0, 1, 0, 0, 1, 1, 0, 0, 2, 1, 1, 1, 0, 1, 0, 0, 0, 1, 1, 0],
       [1, 1, 0, 0, 0, 0, 0, 1, 0, 0, 0, 1, 0, 1, 1, 1, 0, 0, 0, 1, 0],
       [0, 0, 1, 1, 1, 1, 0, 1, 0, 0, 0, 1, 1, 0, 0, 0, 1, 0, 1, 0]]...)
```

In particular the interrogative form “Is this” is only present in the last document:

```
>>> feature_index = bigram_vectorizer.vocabulary_.get('is this')
>>> X_2[:, feature_index]
array([0, 0, 0, 1]...)
```

## Tf-idf term weighting

In a large text corpus, some words will be very present (e.g. “the”, “a”, “is” in English) hence carrying very little meaningful information about the actual contents of the document. If we were to feed the direct count data directly to a classifier those very frequent terms would shadow the frequencies of rarer yet more interesting terms.

In order to re-weight the count features into floating point values suitable for usage by a classifier it is very common to use the tf-idf transform.

Tf means **term-frequency** while tf-idf means term-frequency times **inverse document-frequency**:  $\text{tf-idf}(t,d) = \text{tf}(t,d) \times \text{idf}(t)$ .

Using the `TfidfTransformer`'s default settings, `TfidfTransformer(norm='l2', use_idf=True, smooth_idf=True, sublinear_tf=False)` the term frequency, the number of times a term occurs in a given document, is multiplied with idf component, which is computed as

$$\text{idf}(t) = \log \frac{1+n_d}{1+\text{df}(d,t)} + 1,$$

where  $n_d$  is the total number of documents, and  $\text{df}(d, t)$  is the number of documents that contain term  $t$ . The resulting tf-idf vectors are then normalized by the Euclidean norm:

$$v_{\text{norm}} = \frac{v}{\|v\|_2} = \frac{v}{\sqrt{v_1^2+v_2^2+\dots+v_n^2}}.$$

This was originally a term weighting scheme developed for information retrieval (as a ranking function for search engines results) that has also found good use in document classification and clustering.

The following sections contain further explanations and examples that illustrate how the tf-idfs are computed exactly and how the tf-idfs computed in scikit-learn's `TfidfTransformer` and `TfidfVectorizer` differ slightly from the standard textbook notation that defines the idf as

$$\text{idf}(t) = \log \frac{n_d}{1+\text{df}(d,t)}.$$

In the `TfidfTransformer` and `TfidfVectorizer` with `smooth_idf=False`, the “1” count is added to the idf instead of the idf's denominator:

$$\text{idf}(t) = \log \frac{n_d}{\text{df}(d,t)} + 1$$

This normalization is implemented by the `TfidfTransformer` class:

```
>>> from sklearn.feature_extraction.text import TfidfTransformer
>>> transformer = TfidfTransformer(smooth_idf=False)
>>> transformer
TfidfTransformer(norm='l2', smooth_idf=False, sublinear_tf=False,
                  use_idf=True)
```

Again please see the [reference documentation](#) for the details on all the parameters.

Let's take an example with the following counts. The first term is present 100% of the time hence not very interesting. The two other features only in less than 50% of the time hence probably more representative of the content of the documents:

```
>>> counts = [[3, 0, 1],
...             [2, 0, 0],
...             [3, 0, 0],
...             [4, 0, 0],
...             [3, 2, 0],
...             [3, 0, 2]]
...
>>> tfidf = transformer.fit_transform(counts)
>>> tfidf
<6x3 sparse matrix of type '<... 'numpy.float64'>'>
    with 9 stored elements in Compressed Sparse ... format>

>>> tfidf.toarray()
array([[ 0.81940995,  0.          ,  0.57320793],
       [ 1.          ,  0.          ,  0.          ],
       [ 1.          ,  0.          ,  0.          ],
       [ 1.          ,  0.          ,  0.          ],
       [ 0.47330339,  0.88089948,  0.          ],
       [ 0.58149261,  0.          ,  0.81355169]])
```

Each row is normalized to have unit Euclidean norm:

$$v_{\text{norm}} = \frac{v}{\|v\|_2} = \frac{v}{\sqrt{v_1^2+v_2^2+\dots+v_n^2}}$$

For example, we can compute the tf-idf of the first term in the first document in the `counts` array as follows:

$$n_{d,\text{term1}} = 6$$

$$\text{df}(d, t)_{\text{term1}} = 6$$

$$\text{idf}(d, t)_{\text{term1}} = \log \frac{n_d}{\text{df}(d, t)} + 1 = \log(1) + 1 = 1$$

$$\text{tf-idf}_{\text{term1}} = \text{tf} \times \text{idf} = 3 \times 1 = 3$$

Now, if we repeat this computation for the remaining 2 terms in the document, we get

$$\text{tf-idf}_{\text{term2}} = 0 \times \log(6/1) + 1 = 0$$

$$\text{tf-idf}_{\text{term3}} = 1 \times \log(6/2) + 1 \approx 2.0986$$

and the vector of raw tf-idfs:

$$\text{tf-idf}_{\text{raw}} = [3, 0, 2.0986].$$

Then, applying the Euclidean (L2) norm, we obtain the following tf-idfs for document 1:

$$\frac{[3, 0, 2.0986]}{\sqrt{(3^2+0^2+2.0986^2)}} = [0.819, 0, 0.573].$$

Furthermore, the default parameter `smooth_idf=True` adds “1” to the numerator and denominator as if an extra document was seen containing every term in the collection exactly once, which prevents zero divisions:

$$\text{idf}(t) = \log \frac{1+n_d}{1+\text{df}(d, t)} + 1$$

Using this modification, the tf-idf of the third term in document 1 changes to 1.8473:

$$\text{tf-idf}_{\text{term3}} = 1 \times \log(7/3) + 1 \approx 1.8473$$

And the L2-normalized tf-idf changes to

$$\frac{[3, 0, 1.8473]}{\sqrt{(3^2+0^2+1.8473^2)}} = [0.8515, 0, 0.5243]:$$

```
>>> transformer = TfidfTransformer()
>>> transformer.fit_transform(counts).toarray()
array([[ 0.85151335,  0.          ,  0.52433293],
       [ 1.          ,  0.          ,  0.          ],
       [ 1.          ,  0.          ,  0.          ],
       [ 1.          ,  0.          ,  0.          ],
       [ 0.55422893,  0.83236428,  0.          ],
       [ 0.63035731,  0.          ,  0.77630514]])
```

The weights of each feature computed by the `fit` method call are stored in a model attribute:

```
>>> transformer.idf_
array([ 1. ...,  2.25...,  1.84...])
```

As tf-idf is very often used for text features, there is also another class called `TfidfVectorizer` that combines all the options of `CountVectorizer` and `TfidfTransformer` in a single model:

```
>>> from sklearn.feature_extraction.text import TfidfVectorizer
>>> vectorizer = TfidfVectorizer(min_df=1)
>>> vectorizer.fit_transform(corpus)
...
<4x9 sparse matrix of type '<... 'numpy.float64'>
  with 19 stored elements in Compressed Sparse ... format>
```

While the tf-idf normalization is often very useful, there might be cases where the binary occurrence markers might offer better features. This can be achieved by using the `binary` parameter of `CountVectorizer`. In particular, some estimators such as `Bernoulli Naive Bayes` explicitly model discrete boolean random variables. Also, very short texts are likely to have noisy tf-idf values while the binary occurrence info is more stable.

As usual the best way to adjust the feature extraction parameters is to use a cross-validated grid search, for instance by pipelining the feature extractor with a classifier:

- *Sample pipeline for text feature extraction and evaluation*

## Decoding text files

Text is made of characters, but files are made of bytes. These bytes represent characters according to some *encoding*. To work with text files in Python, their bytes must be *decoded* to a character set called Unicode. Common encodings are ASCII, Latin-1 (Western Europe), KOI8-R (Russian) and the universal encodings UTF-8 and UTF-16. Many others exist.

---

**Note:** An encoding can also be called a ‘character set’, but this term is less accurate: several encodings can exist for a single character set.

---

The text feature extractors in scikit-learn know how to decode text files, but only if you tell them what encoding the files are in. The `CountVectorizer` takes an `encoding` parameter for this purpose. For modern text files, the correct encoding is probably UTF-8, which is therefore the default (`encoding="utf-8"`).

If the text you are loading is not actually encoded with UTF-8, however, you will get a `UnicodeDecodeError`. The vectorizers can be told to be silent about decoding errors by setting the `decode_error` parameter to either "ignore" or "replace". See the documentation for the Python function `bytes.decode` for more details (type `help(bytes.decode)` at the Python prompt).

If you are having trouble decoding text, here are some things to try:

- Find out what the actual encoding of the text is. The file might come with a header or README that tells you the encoding, or there might be some standard encoding you can assume based on where the text comes from.
- You may be able to find out what kind of encoding it is in general using the UNIX command `file`. The Python `chardet` module comes with a script called `chardetect.py` that will guess the specific encoding, though you cannot rely on its guess being correct.
- You could try UTF-8 and disregard the errors. You can decode byte strings with `bytes.decode(errors='replace')` to replace all decoding errors with a meaningless character, or set `decode_error='replace'` in the vectorizer. This may damage the usefulness of your features.
- Real text may come from a variety of sources that may have used different encodings, or even be sloppily decoded in a different encoding than the one it was encoded with. This is common in text retrieved from the Web. The Python package `fity` can automatically sort out some classes of decoding errors, so you could try decoding the unknown text as `latin-1` and then using `fity` to fix errors.
- If the text is in a mish-mash of encodings that is simply too hard to sort out (which is the case for the 20 Newsgroups dataset), you can fall back on a simple single-byte encoding such as `latin-1`. Some text may display incorrectly, but at least the same sequence of bytes will always represent the same feature.

For example, the following snippet uses `chardet` (not shipped with scikit-learn, must be installed separately) to figure out the encoding of three texts. It then vectorizes the texts and prints the learned vocabulary. The output is not shown here.

```
>>> import chardet
>>> text1 = b"Sei mir gegr\xc3\xbc\xc3\x9ft mein Sauerkraut"
```

```

>>> text2 = b"holdselig sind deine Ger\xfcche"
>>> text3 = b"\xff\xfeA\x00u\x00f\x00 \x00F\x001\x00\xfc\x00g\x00e\x001\x00n\x00_
↪\x00d\x00e\x00s\x00 \x00G\x00e\x00s\x00a\x00n\x00g\x00e\x00s\x00, \x00_
↪\x00H\x00e\x00r\x00z\x001\x00i\x00e\x00b\x00c\x00h\x00e\x00n\x00, \x00_
↪\x00t\x00r\x00a\x00g\x00 \x00i\x00c\x00h\x00 \x00d\x00i\x00c\x00h\x00_
↪\x00f\x00o\x00r\x00t\x00"
>>> decoded = [x.decode(chardet.detect(x) ['encoding'])
...         for x in (text1, text2, text3)]
>>> v = CountVectorizer().fit(decoded).vocabulary_
>>> for term in v: print(v)

```

(Depending on the version of chardet, it might get the first one wrong.)

For an introduction to Unicode and character encodings in general, see Joel Spolsky's [Absolute Minimum Every Software Developer Must Know About Unicode](#).

## Applications and examples

The bag of words representation is quite simplistic but surprisingly useful in practice.

In particular in a **supervised setting** it can be successfully combined with fast and scalable linear models to train **document classifiers**, for instance:

- *Classification of text documents using sparse features*

In an **unsupervised setting** it can be used to group similar documents together by applying clustering algorithms such as *K-means*:

- *Clustering text documents using k-means*

Finally it is possible to discover the main topics of a corpus by relaxing the hard assignment constraint of clustering, for instance by using *Non-negative matrix factorization (NMF or NNMF)*:

- sphx\_glr\_auto\_examples\_applications\_topics\_extraction\_with\_nmf\_lda.py

## Limitations of the Bag of Words representation

A collection of unigrams (what bag of words is) cannot capture phrases and multi-word expressions, effectively disregarding any word order dependence. Additionally, the bag of words model doesn't account for potential misspellings or word derivations.

N-grams to the rescue! Instead of building a simple collection of unigrams (n=1), one might prefer a collection of bigrams (n=2), where occurrences of pairs of consecutive words are counted.

One might alternatively consider a collection of character n-grams, a representation resilient against misspellings and derivations.

For example, let's say we're dealing with a corpus of two documents: `['words', 'wprds']`. The second document contains a misspelling of the word 'words'. A simple bag of words representation would consider these two as very distinct documents, differing in both of the two possible features. A character 2-gram representation, however, would find the documents matching in 4 out of 8 features, which may help the preferred classifier decide better:

```

>>> ngram_vectorizer = CountVectorizer(analyzer='char_wb', ngram_range=(2, 2), min_
↪df=1)
>>> counts = ngram_vectorizer.fit_transform(['words', 'wprds'])
>>> ngram_vectorizer.get_feature_names() == (
...     [' w', 'ds', 'or', 'pr', 'rd', 's ', 'wo', 'wp'])
True

```

```
>>> counts.toarray().astype(int)
array([[1, 1, 1, 0, 1, 1, 1, 0],
       [1, 1, 0, 1, 1, 1, 0, 1]])
```

In the above example, 'char\_wb' analyzer is used, which creates n-grams only from characters inside word boundaries (padded with space on each side). The 'char' analyzer, alternatively, creates n-grams that span across words:

```
>>> ngram_vectorizer = CountVectorizer(analyzer='char_wb', ngram_range=(5, 5), min_
->df=1)
>>> ngram_vectorizer.fit_transform(['jumpy fox'])
...
<1x4 sparse matrix of type '<... 'numpy.int64'>'>
    with 4 stored elements in Compressed Sparse ... format>
>>> ngram_vectorizer.get_feature_names() == (
...     ['fox', 'jump', 'jumpy', 'umpy'])
True

>>> ngram_vectorizer = CountVectorizer(analyzer='char', ngram_range=(5, 5), min_df=1)
>>> ngram_vectorizer.fit_transform(['jumpy fox'])
...
<1x5 sparse matrix of type '<... 'numpy.int64'>'>
    with 5 stored elements in Compressed Sparse ... format>
>>> ngram_vectorizer.get_feature_names() == (
...     ['jumpy', 'mpy f', 'py fo', 'umpy ', 'y fox'])
True
```

The word boundaries-aware variant `char_wb` is especially interesting for languages that use white-spaces for word separation as it generates significantly less noisy features than the raw `char` variant in that case. For such languages it can increase both the predictive accuracy and convergence speed of classifiers trained using such features while retaining the robustness with regards to misspellings and word derivations.

While some local positioning information can be preserved by extracting n-grams instead of individual words, bag of words and bag of n-grams destroy most of the inner structure of the document and hence most of the meaning carried by that internal structure.

In order to address the wider task of Natural Language Understanding, the local structure of sentences and paragraphs should thus be taken into account. Many such models will thus be casted as “Structured output” problems which are currently outside of the scope of scikit-learn.

## Vectorizing a large text corpus with the hashing trick

The above vectorization scheme is simple but the fact that it holds an **in- memory mapping from the string tokens to the integer feature indices** (the `vocabulary_` attribute) causes several **problems when dealing with large datasets**:

- the larger the corpus, the larger the vocabulary will grow and hence the memory use too,
- fitting requires the allocation of intermediate data structures of size proportional to that of the original dataset.
- building the word-mapping requires a full pass over the dataset hence it is not possible to fit text classifiers in a strictly online manner.
- pickling and un-pickling vectorizers with a large `vocabulary_` can be very slow (typically much slower than pickling / un-pickling flat data structures such as a NumPy array of the same size),
- it is not easily possible to split the vectorization work into concurrent sub tasks as the `vocabulary_` attribute would have to be a shared state with a fine grained synchronization barrier: the mapping from token string to feature index is dependent on ordering of the first occurrence of each token hence would have to be shared,

potentially harming the concurrent workers' performance to the point of making them slower than the sequential variant.

It is possible to overcome those limitations by combining the “hashing trick” (*Feature hashing*) implemented by the `sklearn.feature_extraction.FeatureHasher` class and the text preprocessing and tokenization features of the `CountVectorizer`.

This combination is implementing in `HashingVectorizer`, a transformer class that is mostly API compatible with `CountVectorizer`. `HashingVectorizer` is stateless, meaning that you don't have to call `fit` on it:

```
>>> from sklearn.feature_extraction.text import HashingVectorizer
>>> hv = HashingVectorizer(n_features=10)
>>> hv.transform(corpus)
...
<4x10 sparse matrix of type '<... 'numpy.float64'>
    with 16 stored elements in Compressed Sparse ... format>
```

You can see that 16 non-zero feature tokens were extracted in the vector output: this is less than the 19 non-zeros extracted previously by the `CountVectorizer` on the same toy corpus. The discrepancy comes from hash function collisions because of the low value of the `n_features` parameter.

In a real world setting, the `n_features` parameter can be left to its default value of `2 ** 20` (roughly one million possible features). If memory or downstream models size is an issue selecting a lower value such as `2 ** 18` might help without introducing too many additional collisions on typical text classification tasks.

Note that the dimensionality does not affect the CPU training time of algorithms which operate on CSR matrices (`LinearSVC(dual=True)`, `Perceptron`, `SGDClassifier`, `PassiveAggressive`) but it does for algorithms that work with CSC matrices (`LinearSVC(dual=False)`, `Lasso()`, etc).

Let's try again with the default setting:

```
>>> hv = HashingVectorizer()
>>> hv.transform(corpus)
...
<4x1048576 sparse matrix of type '<... 'numpy.float64'>
    with 19 stored elements in Compressed Sparse ... format>
```

We no longer get the collisions, but this comes at the expense of a much larger dimensionality of the output space. Of course, other terms than the 19 used here might still collide with each other.

The `HashingVectorizer` also comes with the following limitations:

- it is not possible to invert the model (no `inverse_transform` method), nor to access the original string representation of the features, because of the one-way nature of the hash function that performs the mapping.
- it does not provide IDF weighting as that would introduce statefulness in the model. A `TfidfTransformer` can be appended to it in a pipeline if required.

## Performing out-of-core scaling with HashingVectorizer

An interesting development of using a `HashingVectorizer` is the ability to perform `out-of-core` scaling. This means that we can learn from data that does not fit into the computer's main memory.

A strategy to implement out-of-core scaling is to stream data to the estimator in mini-batches. Each mini-batch is vectorized using `HashingVectorizer` so as to guarantee that the input space of the estimator has always the same dimensionality. The amount of memory used at any time is thus bounded by the size of a mini-batch. Although there is no limit to the amount of data that can be ingested using such an approach, from a practical point of view the learning time is often limited by the CPU time one wants to spend on the task.

For a full-fledged example of out-of-core scaling in a text classification task see [Out-of-core classification of text documents](#).

## Customizing the vectorizer classes

It is possible to customize the behavior by passing a callable to the vectorizer constructor:

```
>>> def my_tokenizer(s):
...     return s.split()
...
>>> vectorizer = CountVectorizer(tokenizer=my_tokenizer)
>>> vectorizer.build_analyzer()(u"Some... punctuation!") == (
...     ['some...', 'punctuation!'])
True
```

In particular we name:

- `preprocessor`: a callable that takes an entire document as input (as a single string), and returns a possibly transformed version of the document, still as an entire string. This can be used to remove HTML tags, lowercase the entire document, etc.
- `tokenizer`: a callable that takes the output from the preprocessor and splits it into tokens, then returns a list of these.
- `analyzer`: a callable that replaces the preprocessor and tokenizer. The default analyzers all call the preprocessor and tokenizer, but custom analyzers will skip this. N-gram extraction and stop word filtering take place at the analyzer level, so a custom analyzer may have to reproduce these steps.

(Lucene users might recognize these names, but be aware that scikit-learn concepts may not map one-to-one onto Lucene concepts.)

To make the preprocessor, tokenizer and analyzers aware of the model parameters it is possible to derive from the class and override the `build_preprocessor`, `build_tokenizer`` and `build_analyzer` factory methods instead of passing custom functions.

Some tips and tricks:

- If documents are pre-tokenized by an external package, then store them in files (or strings) with the tokens separated by whitespace and pass `analyzer=str.split`
- Fancy token-level analysis such as stemming, lemmatizing, compound splitting, filtering based on part-of-speech, etc. are not included in the scikit-learn codebase, but can be added by customizing either the tokenizer or the analyzer. Here's a `CountVectorizer` with a tokenizer and lemmatizer using [NLTK](#):

```
>>> from nltk import word_tokenize
>>> from nltk.stem import WordNetLemmatizer
>>> class LemmaTokenizer(object):
...     def __init__(self):
...         self.wnl = WordNetLemmatizer()
...     def __call__(self, doc):
...         return [self.wnl.lemmatize(t) for t in word_tokenize(doc)]
...
>>> vect = CountVectorizer(tokenizer=LemmaTokenizer())
```

(Note that this will not filter out punctuation.)

Customizing the vectorizer can also be useful when handling Asian languages that do not use an explicit word separator such as whitespace.

## Image feature extraction

### Patch extraction

The `extract_patches_2d` function extracts patches from an image stored as a two-dimensional array, or three-dimensional with color information along the third axis. For rebuilding an image from all its patches, use `reconstruct_from_patches_2d`. For example let's generate a 4x4 pixel picture with 3 color channels (e.g. in RGB format):

```
>>> import numpy as np
>>> from sklearn.feature_extraction import image

>>> one_image = np.arange(4 * 4 * 3).reshape((4, 4, 3))
>>> one_image[:, :, 0] # R channel of a fake RGB picture
array([[ 0,   3,   6,   9],
       [12,  15,  18,  21],
       [24,  27,  30,  33],
       [36,  39,  42,  45]])

>>> patches = image.extract_patches_2d(one_image, (2, 2), max_patches=2,
...     random_state=0)
>>> patches.shape
(2, 2, 2, 3)
>>> patches[:, :, :, 0]
array([[[[ 0,   3],
         [12,  15]],
        [[15,  18],
         [27,  30]]])
>>> patches = image.extract_patches_2d(one_image, (2, 2))
>>> patches.shape
(9, 2, 2, 3)
>>> patches[4, :, :, 0]
array([[15,  18],
       [27,  30]])
```

Let us now try to reconstruct the original image from the patches by averaging on overlapping areas:

```
>>> reconstructed = image.reconstruct_from_patches_2d(patches, (4, 4, 3))
>>> np.testing.assert_array_equal(one_image, reconstructed)
```

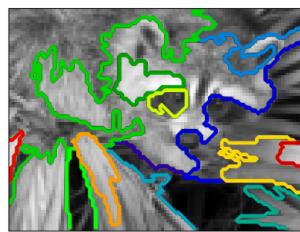

The `PatchExtractor` class works in the same way as `extract_patches_2d`, only it supports multiple images as input. It is implemented as an estimator, so it can be used in pipelines. See:

```
>>> five_images = np.arange(5 * 4 * 4 * 3).reshape(5, 4, 4, 3)
>>> patches = image.PatchExtractor((2, 2)).transform(five_images)
>>> patches.shape
(45, 2, 2, 3)
```

### Connectivity graph of an image

Several estimators in the scikit-learn can use connectivity information between features or samples. For instance Ward clustering ([Hierarchical clustering](#)) can cluster together only neighboring pixels of an image, thus forming contiguous patches:

For this purpose, the estimators use a ‘connectivity’ matrix, giving which samples are connected.

The function `img_to_graph` returns such a matrix from a 2D or 3D image. Similarly, `grid_to_graph` build a connectivity matrix for images given the shape of these image.

These matrices can be used to impose connectivity in estimators that use connectivity information, such as Ward clustering ([Hierarchical clustering](#)), but also to build precomputed kernels, or similarity matrices.

---

#### Note: Examples

- [A demo of structured Ward hierarchical clustering on a raccoon face image](#)
  - [Spectral clustering for image segmentation](#)
  - [Feature agglomeration vs. univariate selection](#)
- 

### 3.4.3 Preprocessing data

The `sklearn.preprocessing` package provides several common utility functions and transformer classes to change raw feature vectors into a representation that is more suitable for the downstream estimators.

#### Standardization, or mean removal and variance scaling

**Standardization** of datasets is a **common requirement for many machine learning estimators** implemented in scikit-learn; they might behave badly if the individual features do not more or less look like standard normally distributed data: Gaussian with **zero mean and unit variance**.

In practice we often ignore the shape of the distribution and just transform the data to center it by removing the mean value of each feature, then scale it by dividing non-constant features by their standard deviation.

For instance, many elements used in the objective function of a learning algorithm (such as the RBF kernel of Support Vector Machines or the l1 and l2 regularizers of linear models) assume that all features are centered around zero and have variance in the same order. If a feature has a variance that is orders of magnitude larger than others, it might dominate the objective function and make the estimator unable to learn from other features correctly as expected.

The function `scale` provides a quick and easy way to perform this operation on a single array-like dataset:

```
>>> from sklearn import preprocessing
>>> import numpy as np
>>> X = np.array([[ 1., -1.,  2.],
...               [ 2.,  0.,  0.],
...               [ 0.,  1., -1.]])
>>> X_scaled = preprocessing.scale(X)
```

```
>>> X_scaled
array([[ 0. ..., -1.22...,  1.33...],
       [ 1.22...,  0. ..., -0.26...],
       [-1.22...,  1.22..., -1.06...]])
```

Scaled data has zero mean and unit variance:

```
>>> X_scaled.mean(axis=0)
array([ 0.,  0.,  0.])

>>> X_scaled.std(axis=0)
array([ 1.,  1.,  1.])
```

The preprocessing module further provides a utility class [StandardScaler](#) that implements the Transformer API to compute the mean and standard deviation on a training set so as to be able to later reapply the same transformation on the testing set. This class is hence suitable for use in the early steps of a [sklearn.pipeline.Pipeline](#):

```
>>> scaler = preprocessing.StandardScaler().fit(X)
>>> scaler
StandardScaler(copy=True, with_mean=True, with_std=True)

>>> scaler.mean_
array([ 1. ...,  0. ...,  0.33...])

>>> scaler.scale_
array([ 0.81...,  0.81...,  1.24...])

>>> scaler.transform(X)
array([[ 0. ..., -1.22...,  1.33...],
       [ 1.22...,  0. ..., -0.26...],
       [-1.22...,  1.22..., -1.06...]])
```

The scaler instance can then be used on new data to transform it the same way it did on the training set:

```
>>> scaler.transform([-1.,  1.,  0.])
array([-2.44...,  1.22..., -0.26...])
```

It is possible to disable either centering or scaling by either passing `with_mean=False` or `with_std=False` to the constructor of [StandardScaler](#).

## Scaling features to a range

An alternative standardization is scaling features to lie between a given minimum and maximum value, often between zero and one, or so that the maximum absolute value of each feature is scaled to unit size. This can be achieved using [MinMaxScaler](#) or [MaxAbsScaler](#), respectively.

The motivation to use this scaling include robustness to very small standard deviations of features and preserving zero entries in sparse data.

Here is an example to scale a toy data matrix to the  $[0, 1]$  range:

```
>>> X_train = np.array([[ 1., -1.,  2.],
...                      [ 2.,  0.,  0.],
...                      [ 0.,  1., -1.]])
```

```

...
>>> min_max_scaler = preprocessing.MinMaxScaler()
>>> X_train_minmax = min_max_scaler.fit_transform(X_train)
>>> X_train_minmax
array([[ 0.5        ,  0.          ,  1.          ],
       [ 1.        ,  0.5        ,  0.33333333],
       [ 0.        ,  1.          ,  0.          ]])

```

The same instance of the transformer can then be applied to some new test data unseen during the fit call: the same scaling and shifting operations will be applied to be consistent with the transformation performed on the train data:

```

>>> X_test = np.array([[ -3., -1.,  4.]])
>>> X_test_minmax = min_max_scaler.transform(X_test)
>>> X_test_minmax
array([-1.5        ,  0.          ,  1.66666667])

```

It is possible to introspect the scaler attributes to find about the exact nature of the transformation learned on the training data:

```

>>> min_max_scaler.scale_
array([ 0.5        ,  0.5        ,  0.33...])

>>> min_max_scaler.min_
array([ 0.        ,  0.5        ,  0.33...])

```

If `MinMaxScaler` is given an explicit `feature_range=(min, max)` the full formula is:

```

X_std = (X - X.min(axis=0)) / (X.max(axis=0) - X.min(axis=0))

X_scaled = X_std * (max - min) + min

```

`MaxAbsScaler` works in a very similar fashion, but scales in a way that the training data lies within the range  $[-1, 1]$  by dividing through the largest maximum value in each feature. It is meant for data that is already centered at zero or sparse data.

Here is how to use the toy data from the previous example with this scaler:

```

...
>>> X_train = np.array([[ 1., -1.,  2.],
...                     [ 2.,  0.,  0.],
...                     [ 0.,  1., -1.]])
...
>>> max_abs_scaler = preprocessing.MaxAbsScaler()
>>> X_train_maxabs = max_abs_scaler.fit_transform(X_train)
>>> X_train_maxabs
array([[ 0.5, -1. ,  1. ],
       [ 1. ,  0. ,  0. ],
       [ 0. ,  1. , -0.5]])
>>> X_test = np.array([[ -3., -1.,  4.]])
>>> X_test_maxabs = max_abs_scaler.transform(X_test)
>>> X_test_maxabs
array([-1.5, -1. ,  2. ])
>>> max_abs_scaler.scale_
array([ 2.,  1.,  2.])

```

As with `scale`, the module further provides convenience functions `minmax_scale` and `maxabs_scale` if you don't want to create an object.

## Scaling sparse data

Centering sparse data would destroy the sparseness structure in the data, and thus rarely is a sensible thing to do. However, it can make sense to scale sparse inputs, especially if features are on different scales.

`MaxAbsScaler` and `maxabs_scale` were specifically designed for scaling sparse data, and are the recommended way to go about this. However, `scale` and `StandardScaler` can accept `scipy.sparse` matrices as input, as long as `with_mean=False` is explicitly passed to the constructor. Otherwise a `ValueError` will be raised as silently centering would break the sparsity and would often crash the execution by allocating excessive amounts of memory unintentionally. `RobustScaler` cannot be fitted to sparse inputs, but you can use the `transform` method on sparse inputs.

Note that the scalers accept both Compressed Sparse Rows and Compressed Sparse Columns format (see `scipy.sparse.csr_matrix` and `scipy.sparse.csc_matrix`). Any other sparse input will be **converted to the Compressed Sparse Rows representation**. To avoid unnecessary memory copies, it is recommended to choose the CSR or CSC representation upstream.

Finally, if the centered data is expected to be small enough, explicitly converting the input to an array using the `toarray` method of sparse matrices is another option.

## Scaling data with outliers

If your data contains many outliers, scaling using the mean and variance of the data is likely to not work very well. In these cases, you can use `robust_scale` and `RobustScaler` as drop-in replacements instead. They use more robust estimates for the center and range of your data.

### References:

Further discussion on the importance of centering and scaling data is available on this FAQ: Should I normalize/standardize/rescale the data?

### Scaling vs Whitening

It is sometimes not enough to center and scale the features independently, since a downstream model can further make some assumption on the linear independence of the features.

To address this issue you can use `sklearn.decomposition.PCA` or `sklearn.decomposition.RandomizedPCA` with `whiten=True` to further remove the linear correlation across features.

### Scaling target variables in regression

`scale` and `StandardScaler` work out-of-the-box with 1d arrays. This is very useful for scaling the target / response variables used for regression.

## Centering kernel matrices

If you have a kernel matrix of a kernel  $K$  that computes a dot product in a feature space defined by function  $\phi$ , a `KernelCenterer` can transform the kernel matrix so that it contains inner products in the feature space defined by  $\phi$  followed by removal of the mean in that space.

## Normalization

**Normalization** is the process of **scaling individual samples to have unit norm**. This process can be useful if you plan to use a quadratic form such as the dot-product or any other kernel to quantify the similarity of any pair of samples.

This assumption is the base of the **Vector Space Model** often used in text classification and clustering contexts.

The function `normalize` provides a quick and easy way to perform this operation on a single array-like dataset, either using the 11 or 12 norms:

```
>>> X = [[ 1., -1.,  2.],
...       [ 2.,  0.,  0.],
...       [ 0.,  1., -1.]]
>>> X_normalized = preprocessing.normalize(X, norm='l2')

>>> X_normalized
array([[ 0.40..., -0.40...,  0.81...],
       [ 1. ...,  0. ...,  0. ...],
       [ 0. ...,  0.70..., -0.70...]])
```

The `preprocessing` module further provides a utility class `Normalizer` that implements the same operation using the Transformer API (even though the `fit` method is useless in this case: the class is stateless as this operation treats samples independently).

This class is hence suitable for use in the early steps of a `sklearn.pipeline.Pipeline`:

```
>>> normalizer = preprocessing.Normalizer().fit(X) # fit does nothing
>>> normalizer
Normalizer(copy=True, norm='l2')
```

The `normalizer` instance can then be used on sample vectors as any transformer:

```
>>> normalizer.transform(X)
array([[ 0.40..., -0.40...,  0.81...],
       [ 1. ...,  0. ...,  0. ...],
       [ 0. ...,  0.70..., -0.70...]])

>>> normalizer.transform([-1.,  1.,  0.])
array([[-0.70...,  0.70...,  0. ...]])
```

## Sparse input

`normalize` and `Normalizer` accept **both dense array-like and sparse matrices from `scipy.sparse` as input**.

For sparse input the data is **converted to the Compressed Sparse Rows representation** (see `scipy.sparse.csr_matrix`) before being fed to efficient Cython routines. To avoid unnecessary memory copies, it is recommended to choose the CSR representation upstream.

## Binarization

### Feature binarization

**Feature binarization** is the process of **thresholding numerical features to get boolean values**. This can be useful for downstream probabilistic estimators that make assumption that the input data is distributed according to a multi-variate Bernoulli distribution. For instance, this is the case for the `sklearn.neural_network.BernoulliRBM`.

It is also common among the text processing community to use binary feature values (probably to simplify the probabilistic reasoning) even if normalized counts (a.k.a. term frequencies) or TF-IDF valued features often perform slightly better in practice.

As for the [Normalizer](#), the utility class [Binarizer](#) is meant to be used in the early stages of [sklearn.pipeline.Pipeline](#). The fit method does nothing as each sample is treated independently of others:

```
>>> X = [[ 1., -1.,  2.],
...       [ 2.,  0.,  0.],
...       [ 0.,  1., -1.]]  
  
>>> binarizer = preprocessing.Binarizer().fit(X)  # fit does nothing  
>>> binarizer  
Binarizer(copy=True, threshold=0.0)  
  
>>> binarizer.transform(X)  
array([[ 1.,  0.,  1.],  
       [ 1.,  0.,  0.],  
       [ 0.,  1.,  0.]])
```

It is possible to adjust the threshold of the binarizer:

```
>>> binarizer = preprocessing.Binarizer(threshold=1.1)  
>>> binarizer.transform(X)  
array([[ 0.,  0.,  1.],  
       [ 1.,  0.,  0.],  
       [ 0.,  0.,  0.]])
```

As for the [StandardScaler](#) and [Normalizer](#) classes, the preprocessing module provides a companion function [binarize](#) to be used when the transformer API is not necessary.

### Sparse input

[binarize](#) and [Binarizer](#) accept **both dense array-like and sparse matrices from `scipy.sparse` as input**.

For sparse input the data is **converted to the Compressed Sparse Rows representation** (see `scipy.sparse.csr_matrix`). To avoid unnecessary memory copies, it is recommended to choose the CSR representation upstream.

### Encoding categorical features

Often features are not given as continuous values but categorical. For example a person could have features ["male", "female"], ["from Europe", "from US", "from Asia"], ["uses Firefox", "uses Chrome", "uses Safari", "uses Internet Explorer"]. Such features can be efficiently coded as integers, for instance ["male", "from US", "uses Internet Explorer"] could be expressed as [0, 1, 3] while ["female", "from Asia", "uses Chrome"] would be [1, 2, 1].

Such integer representation can not be used directly with scikit-learn estimators, as these expect continuous input, and would interpret the categories as being ordered, which is often not desired (i.e. the set of browsers was ordered arbitrarily).

One possibility to convert categorical features to features that can be used with scikit-learn estimators is to use a one-of-K or one-hot encoding, which is implemented in [OneHotEncoder](#). This estimator transforms each categorical feature with  $m$  possible values into  $m$  binary features, with only one active.

Continuing the example above:

```
>>> enc = preprocessing.OneHotEncoder()
>>> enc.fit([[0, 0, 3], [1, 1, 0], [0, 2, 1], [1, 0, 2]])
OneHotEncoder(categorical_features='all', dtype=<... 'numpy.float64'>,
               handle_unknown='error', n_values='auto', sparse=True)
>>> enc.transform([[0, 1, 3]]).toarray()
array([[ 1.,  0.,  0.,  1.,  0.,  0.,  0.,  1.]])
```

By default, how many values each feature can take is inferred automatically from the dataset. It is possible to specify this explicitly using the parameter `n_values`. There are two genders, three possible continents and four web browsers in our dataset. Then we fit the estimator, and transform a data point. In the result, the first two numbers encode the gender, the next set of three numbers the continent and the last four the web browser.

Note that, if there is a possibility that the training data might have missing categorical features, one has to explicitly set `n_values`. For example,

```
>>> enc = preprocessing.OneHotEncoder(n_values=[2, 3, 4])
>>> # Note that there are missing categorical values for the 2nd and 3rd
>>> # features
>>> enc.fit([[1, 2, 3], [0, 2, 0]])
OneHotEncoder(categorical_features='all', dtype=<... 'numpy.float64'>,
               handle_unknown='error', n_values=[2, 3, 4], sparse=True)
>>> enc.transform([[1, 0, 0]]).toarray()
array([[ 0.,  1.,  1.,  0.,  1.,  0.,  0.,  0.]])
```

See [Loading features from dicts](#) for categorical features that are represented as a dict, not as integers.

## Imputation of missing values

For various reasons, many real world datasets contain missing values, often encoded as blanks, NaNs or other placeholders. Such datasets however are incompatible with scikit-learn estimators which assume that all values in an array are numerical, and that all have and hold meaning. A basic strategy to use incomplete datasets is to discard entire rows and/or columns containing missing values. However, this comes at the price of losing data which may be valuable (even though incomplete). A better strategy is to impute the missing values, i.e., to infer them from the known part of the data.

The `Imputer` class provides basic strategies for imputing missing values, either using the mean, the median or the most frequent value of the row or column in which the missing values are located. This class also allows for different missing values encodings.

The following snippet demonstrates how to replace missing values, encoded as `np.nan`, using the mean value of the columns (axis 0) that contain the missing values:

```
>>> import numpy as np
>>> from sklearn.preprocessing import Imputer
>>> imp = Imputer(missing_values='NaN', strategy='mean', axis=0)
>>> imp.fit([[1, 2], [np.nan, 3], [7, 6]])
Imputer(axis=0, copy=True, missing_values='NaN', strategy='mean', verbose=0)
>>> X = [[np.nan, 2], [6, np.nan], [7, 6]]
>>> print(imp.transform(X))
[[ 4.          2.        ]
 [ 6.          3.666...]
 [ 7.          6.        ]]
```

The `Imputer` class also supports sparse matrices:

```
>>> import scipy.sparse as sp
>>> X = sp.csc_matrix([[1, 2], [0, 3], [7, 6]])
```

```
>>> imp = Imputer(missing_values=0, strategy='mean', axis=0)
>>> imp.fit(X)
Imputer(axis=0, copy=True, missing_values=0, strategy='mean', verbose=0)
>>> X_test = sp.csc_matrix([[0, 2], [6, 0], [7, 6]])
>>> print(imp.transform(X_test))
[[ 4.          2.          ]
 [ 6.          3.666...]
 [ 7.          6.          ]]
```

Note that, here, missing values are encoded by 0 and are thus implicitly stored in the matrix. This format is thus suitable when there are many more missing values than observed values.

`Imputer` can be used in a Pipeline as a way to build a composite estimator that supports imputation. See `sphx_glr_auto_examples_missing_values.py`

## Generating polynomial features

Often it's useful to add complexity to the model by considering nonlinear features of the input data. A simple and common method to use is polynomial features, which can get features' high-order and interaction terms. It is implemented in `PolynomialFeatures`:

```
>>> import numpy as np
>>> from sklearn.preprocessing import PolynomialFeatures
>>> X = np.arange(6).reshape(3, 2)
>>> X
array([[0, 1],
       [2, 3],
       [4, 5]])
>>> poly = PolynomialFeatures(2)
>>> poly.fit_transform(X)
array([[ 1.,    0.,    1.,    0.,    0.,    1.],
       [ 1.,    2.,    3.,    4.,    6.,    9.],
       [ 1.,    4.,    5.,   16.,   20.,   25.]])
```

The features of X have been transformed from  $(X_1, X_2)$  to  $(1, X_1, X_2, X_1^2, X_1X_2, X_2^2)$ .

In some cases, only interaction terms among features are required, and it can be gotten with the setting `interaction_only=True`:

```
>>> X = np.arange(9).reshape(3, 3)
>>> X
array([[0, 1, 2],
       [3, 4, 5],
       [6, 7, 8]])
>>> poly = PolynomialFeatures(degree=3, interaction_only=True)
>>> poly.fit_transform(X)
array([[ 1.,    0.,    1.,    2.,    0.,    0.,    2.,    0.],
       [ 1.,    3.,    4.,    5.,   12.,   15.,   20.,   60.],
       [ 1.,    6.,    7.,    8.,   42.,   48.,   56.,  336.]])
```

The features of X have been transformed from  $(X_1, X_2, X_3)$  to  $(1, X_1, X_2, X_3, X_1X_2, X_1X_3, X_2X_3, X_1X_2X_3)$ .

Note that polynomial features are used implicitly in kernel methods (e.g., `sklearn.svm.SVC`, `sklearn.decomposition.KernelPCA`) when using polynomial `Kernel functions`.

See `Polynomial interpolation` for Ridge regression using created polynomial features.

## Custom transformers

Often, you will want to convert an existing Python function into a transformer to assist in data cleaning or processing. You can implement a transformer from an arbitrary function with [FunctionTransformer](#). For example, to build a transformer that applies a log transformation in a pipeline, do:

```
>>> import numpy as np
>>> from sklearn.preprocessing import FunctionTransformer
>>> transformer = FunctionTransformer(np.log1p)
>>> X = np.array([[0, 1], [2, 3]])
>>> transformer.transform(X)
array([[ 0.          ,  0.69314718],
       [ 1.09861229,  1.38629436]])
```

For a full code example that demonstrates using a [FunctionTransformer](#) to do custom feature selection, see [Using FunctionTransformer to select columns](#)

### 3.4.4 Unsupervised dimensionality reduction

If your number of features is high, it may be useful to reduce it with an unsupervised step prior to supervised steps. Many of the [Unsupervised learning](#) methods implement a `transform` method that can be used to reduce the dimensionality. Below we discuss two specific example of this pattern that are heavily used.

#### Pipelining

The unsupervised data reduction and the supervised estimator can be chained in one step. See [Pipeline: chaining estimators](#).

#### PCA: principal component analysis

`decomposition.PCA` looks for a combination of features that capture well the variance of the original features. See [Decomposing signals in components \(matrix factorization problems\)](#).

#### Examples

- sphx\_glr\_auto\_examples\_applications\_face\_recognition.py

#### Random projections

The module: `random_projection` provides several tools for data reduction by random projections. See the relevant section of the documentation: [Random Projection](#).

#### Examples

- [The Johnson-Lindenstrauss bound for embedding with random projections](#)

## Feature agglomeration

`cluster.FeatureAgglomeration` applies *Hierarchical clustering* to group together features that behave similarly.

### Examples

- *Feature agglomeration vs. univariate selection*
- *Feature agglomeration*

## Feature scaling

Note that if features have very different scaling or statistical properties, `cluster.FeatureAgglomeration` may not be able to capture the links between related features. Using a `preprocessing.StandardScaler` can be useful in these settings.

## 3.4.5 Random Projection

The `sklearn.random_projection` module implements a simple and computationally efficient way to reduce the dimensionality of the data by trading a controlled amount of accuracy (as additional variance) for faster processing times and smaller model sizes. This module implements two types of unstructured random matrix: *Gaussian random matrix* and *sparse random matrix*.

The dimensions and distribution of random projections matrices are controlled so as to preserve the pairwise distances between any two samples of the dataset. Thus random projection is a suitable approximation technique for distance based method.

## The Johnson-Lindenstrauss lemma

The main theoretical result behind the efficiency of random projection is the Johnson-Lindenstrauss lemma (quoting Wikipedia):

In mathematics, the Johnson-Lindenstrauss lemma is a result concerning low-distortion embeddings of points from high-dimensional into low-dimensional Euclidean space. The lemma states that a small set of points in a high-dimensional space can be embedded into a space of much lower dimension in such a way that distances between the points are nearly preserved. The map used for the embedding is at least Lipschitz, and can even be taken to be an orthogonal projection.

Knowing only the number of samples, the `sklearn.random_projection.johnson_lindenstrauss_min_dim` estimates conservatively the minimal size of the random subspace to guarantee a bounded distortion introduced by the random projection:

```
>>> from sklearn.random_projection import johnson_lindenstrauss_min_dim
>>> johnson_lindenstrauss_min_dim(n_samples=1e6, eps=0.5)
663
>>> johnson_lindenstrauss_min_dim(n_samples=1e6, eps=[0.5, 0.1, 0.01])
array([ 663, 11841, 1112658])
>>> johnson_lindenstrauss_min_dim(n_samples=[1e4, 1e5, 1e6], eps=0.1)
array([ 7894, 9868, 11841])
```

#### Example:

- See [The Johnson-Lindenstrauss bound for embedding with random projections](#) for a theoretical explication on the Johnson-Lindenstrauss lemma and an empirical validation using sparse random matrices.

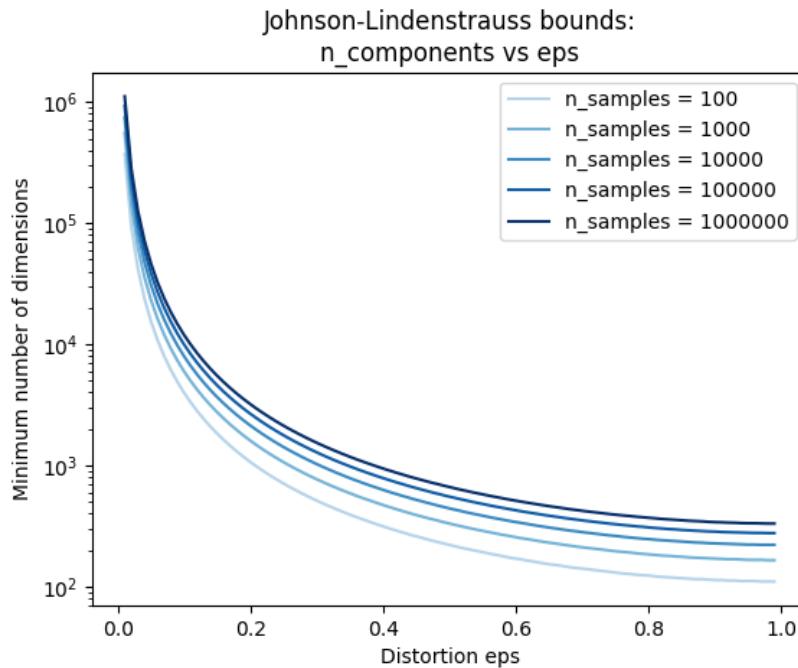

#### References:

- Sanjoy Dasgupta and Anupam Gupta, 1999. [An elementary proof of the Johnson-Lindenstrauss Lemma](#).

## Gaussian random projection

The `sklearn.random_projection.GaussianRandomProjection` reduces the dimensionality by projecting the original input space on a randomly generated matrix where components are drawn from the following distribution  $N(0, \frac{1}{n_{components}})$ .

Here a small excerpt which illustrates how to use the Gaussian random projection transformer:

```
>>> import numpy as np
>>> from sklearn import random_projection
>>> X = np.random.rand(100, 10000)
>>> transformer = random_projection.GaussianRandomProjection()
>>> X_new = transformer.fit_transform(X)
>>> X_new.shape
(100, 3947)
```

## Sparse random projection

The `sklearn.random_projection.SparseRandomProjection` reduces the dimensionality by projecting the original input space using a sparse random matrix.

Sparse random matrices are an alternative to dense Gaussian random projection matrix that guarantees similar embedding quality while being much more memory efficient and allowing faster computation of the projected data.

If we define  $s = 1 / \text{density}$ , the elements of the random matrix are drawn from

$$\begin{cases} -\sqrt{\frac{s}{n_{\text{components}}}} & 1/2s \\ 0 & \text{with probability } 1 - 1/s \\ +\sqrt{\frac{s}{n_{\text{components}}}} & 1/2s \end{cases}$$

where  $n_{\text{components}}$  is the size of the projected subspace. By default the density of non zero elements is set to the minimum density as recommended by Ping Li et al.:  $1/\sqrt{n_{\text{features}}}$ .

Here a small excerpt which illustrates how to use the sparse random projection transformer:

```
>>> import numpy as np
>>> from sklearn import random_projection
>>> X = np.random.rand(100,10000)
>>> transformer = random_projection.SparseRandomProjection()
```

```
>>> X_new = transformer.fit_transform(X)
>>> X_new.shape
(100, 3947)
```

### 3.4.6 Kernel Approximation

This submodule contains functions that approximate the feature mappings that correspond to certain kernels, as they are used for example in support vector machines (see [Support Vector Machines](#)). The following feature functions perform non-linear transformations of the input, which can serve as a basis for linear classification or other algorithms.

The advantage of using approximate explicit feature maps compared to the [kernel trick](#), which makes use of feature maps implicitly, is that explicit mappings can be better suited for online learning and can significantly reduce the cost of learning with very large datasets. Standard kernelized SVMs do not scale well to large datasets, but using an approximate kernel map it is possible to use much more efficient linear SVMs. In particular, the combination of kernel map approximations with [SGDClassifier](#) can make non-linear learning on large datasets possible.

Since there has not been much empirical work using approximate embeddings, it is advisable to compare results against exact kernel methods when possible.

**See also:**

[Polynomial regression: extending linear models with basis functions](#) for an exact polynomial transformation.

#### Nystroem Method for Kernel Approximation

The Nystroem method, as implemented in [Nystroem](#) is a general method for low-rank approximations of kernels. It achieves this by essentially subsampling the data on which the kernel is evaluated. By default [Nystroem](#) uses the rbf kernel, but it can use any kernel function or a precomputed kernel matrix. The number of samples used - which is also the dimensionality of the features computed - is given by the parameter n\_components.

#### Radial Basis Function Kernel

The [RBFSampler](#) constructs an approximate mapping for the radial basis function kernel, also known as *Random Kitchen Sinks* [RR2007]. This transformation can be used to explicitly model a kernel map, prior to applying a linear algorithm, for example a linear SVM:

```
>>> from sklearn.kernel_approximation import RBFSampler
>>> from sklearn.linear_model import SGDClassifier
>>> X = [[0, 0], [1, 1], [1, 0], [0, 1]]
>>> y = [0, 0, 1, 1]
>>> rbf_feature = RBFSampler(gamma=1, random_state=1)
>>> X_features = rbf_feature.fit_transform(X)
>>> clf = SGDClassifier()
>>> clf.fit(X_features, y)
```

```

SGDClassifier(alpha=0.0001, average=False, class_weight=None, epsilon=0.1,
    eta0=0.0, fit_intercept=True, l1_ratio=0.15,
    learning_rate='optimal', loss='hinge', n_iter=5, n_jobs=1,
    penalty='l2', power_t=0.5, random_state=None, shuffle=True,
    verbose=0, warm_start=False)
>>> clf.score(X_features, y)
1.0

```

The mapping relies on a Monte Carlo approximation to the kernel values. The `fit` function performs the Monte Carlo sampling, whereas the `transform` method performs the mapping of the data. Because of the inherent randomness of the process, results may vary between different calls to the `fit` function.

The `fit` function takes two arguments: `n_components`, which is the target dimensionality of the feature transform, and `gamma`, the parameter of the RBF-kernel. A higher `n_components` will result in a better approximation of the kernel and will yield results more similar to those produced by a kernel SVM. Note that “fitting” the feature function does not actually depend on the data given to the `fit` function. Only the dimensionality of the data is used. Details on the method can be found in [RR2007].

For a given value of `n_components` `RBFSampler` is often less accurate as `Nystroem`. `RBFSampler` is cheaper to compute, though, making use of larger feature spaces more efficient.

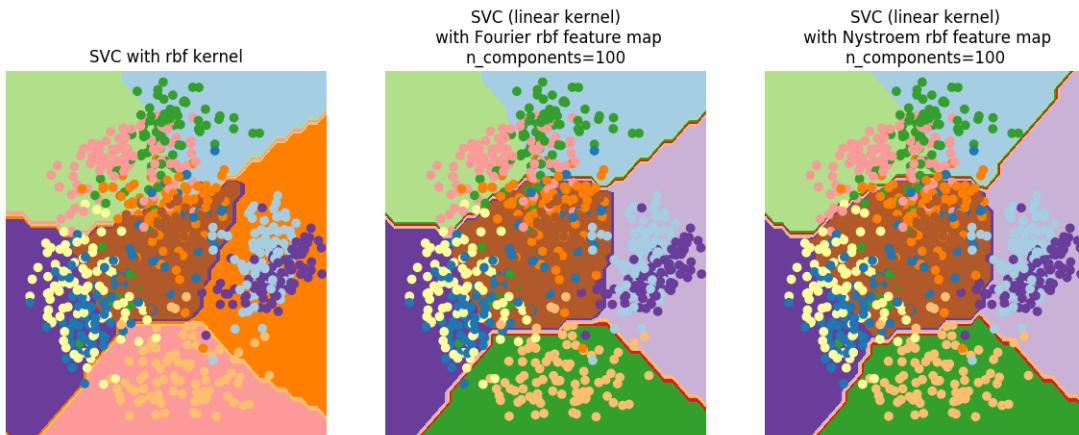

Fig. 3.9: Comparing an exact RBF kernel (left) with the approximation (right)

### Examples:

- *Explicit feature map approximation for RBF kernels*

### Additive Chi Squared Kernel

The additive chi squared kernel is a kernel on histograms, often used in computer vision.

The additive chi squared kernel as used here is given by

$$k(x, y) = \sum_i \frac{2x_i y_i}{x_i + y_i}$$

This is not exactly the same as `sklearn.metrics.additive_chi2_kernel`. The authors of [VZ2010] prefer the version above as it is always positive definite. Since the kernel is additive, it is possible to treat all components  $x_i$  separately for embedding. This makes it possible to sample the Fourier transform in regular intervals, instead of approximating using Monte Carlo sampling.

The class `AdditiveChi2Sampler` implements this component wise deterministic sampling. Each component is sampled  $n$  times, yielding  $2n + 1$  dimensions per input dimension (the multiple of two stems from the real and complex part of the Fourier transform). In the literature,  $n$  is usually chosen to be 1 or 2, transforming the dataset to size `n_samples * 5 * n_features` (in the case of  $n = 2$ ).

The approximate feature map provided by `AdditiveChi2Sampler` can be combined with the approximate feature map provided by `RBFSampler` to yield an approximate feature map for the exponentiated chi squared kernel. See the [VZ2010] for details and [VVZ2010] for combination with the `RBFSampler`.

## Skewed Chi Squared Kernel

The skewed chi squared kernel is given by:

$$k(x, y) = \prod_i \frac{2\sqrt{x_i + c}\sqrt{y_i + c}}{x_i + y_i + 2c}$$

It has properties that are similar to the exponentiated chi squared kernel often used in computer vision, but allows for a simple Monte Carlo approximation of the feature map.

The usage of the `SkewedChi2Sampler` is the same as the usage described above for the `RBFSampler`. The only difference is in the free parameter, that is called  $c$ . For a motivation for this mapping and the mathematical details see [LS2010].

## Mathematical Details

Kernel methods like support vector machines or kernelized PCA rely on a property of reproducing kernel Hilbert spaces. For any positive definite kernel function  $k$  (a so called Mercer kernel), it is guaranteed that there exists a mapping  $\phi$  into a Hilbert space  $\mathcal{H}$ , such that

$$k(x, y) = \langle \phi(x), \phi(y) \rangle$$

Where  $\langle \cdot, \cdot \rangle$  denotes the inner product in the Hilbert space.

If an algorithm, such as a linear support vector machine or PCA, relies only on the scalar product of data points  $x_i$ , one may use the value of  $k(x_i, x_j)$ , which corresponds to applying the algorithm to the mapped data points  $\phi(x_i)$ . The advantage of using  $k$  is that the mapping  $\phi$  never has to be calculated explicitly, allowing for arbitrary large features (even infinite).

One drawback of kernel methods is, that it might be necessary to store many kernel values  $k(x_i, x_j)$  during optimization. If a kernelized classifier is applied to new data  $y_j$ ,  $k(x_i, y_j)$  needs to be computed to make predictions, possibly for many different  $x_i$  in the training set.

The classes in this submodule allow to approximate the embedding  $\phi$ , thereby working explicitly with the representations  $\phi(x_i)$ , which obviates the need to apply the kernel or store training examples.

### 3.4.7 Pairwise metrics, Affinities and Kernels

The `sklearn.metrics.pairwise` submodule implements utilities to evaluate pairwise distances or affinity of sets of samples.

This module contains both distance metrics and kernels. A brief summary is given on the two here.

Distance metrics are functions  $d(a, b)$  such that  $d(a, b) < d(a, c)$  if objects  $a$  and  $b$  are considered “more similar” than objects  $a$  and  $c$ . Two objects exactly alike would have a distance of zero. One of the most popular examples is Euclidean distance. To be a ‘true’ metric, it must obey the following four conditions:

1.  $d(a, b) \geq 0$ , for all  $a$  and  $b$
2.  $d(a, b) = 0$ , if and only if  $a = b$ , positive definiteness
3.  $d(a, b) = d(b, a)$ , symmetry
4.  $d(a, c) \leq d(a, b) + d(b, c)$ , the triangle inequality

Kernels are measures of similarity, i.e.  $s(a, b) > s(a, c)$  if objects  $a$  and  $b$  are considered “more similar” than objects  $a$  and  $c$ . A kernel must also be positive semi-definite.

There are a number of ways to convert between a distance metric and a similarity measure, such as a kernel. Let  $D$  be the distance, and  $S$  be the kernel:

1.  $S = np.exp(-D * \text{gamma})$ , where one heuristic for choosing gamma is  $1 / \text{num\_features}$
2.  $S = 1. / (D / np.max(D))$

#### Cosine similarity

`cosine_similarity` computes the L2-normalized dot product of vectors. That is, if  $x$  and  $y$  are row vectors, their cosine similarity  $k$  is defined as:

$$k(x, y) = \frac{xy^\top}{\|x\|\|y\|}$$

This is called cosine similarity, because Euclidean (L2) normalization projects the vectors onto the unit sphere, and their dot product is then the cosine of the angle between the points denoted by the vectors.

This kernel is a popular choice for computing the similarity of documents represented as tf-idf vectors. `cosine_similarity` accepts `scipy.sparse` matrices. (Note that the tf-idf functionality in `sklearn.feature_extraction.text` can produce normalized vectors, in which case `cosine_similarity` is equivalent to `linear_kernel`, only slower.)

#### References:

- C.D. Manning, P. Raghavan and H. Schütze (2008). Introduction to Information Retrieval. Cambridge University Press. <http://nlp.stanford.edu/IR-book/html/htmledition/the-vector-space-model-for-scoring-1.html>

#### Linear kernel

The function `linear_kernel` computes the linear kernel, that is, a special case of `polynomial_kernel` with `degree=1` and `coef0=0` (homogeneous). If  $x$  and  $y$  are column vectors, their linear kernel is:

$$k(x, y) = x^\top y$$

## Polynomial kernel

The function `polynomial_kernel` computes the degree-d polynomial kernel between two vectors. The polynomial kernel represents the similarity between two vectors. Conceptually, the polynomial kernels considers not only the similarity between vectors under the same dimension, but also across dimensions. When used in machine learning algorithms, this allows to account for feature interaction.

The polynomial kernel is defined as:

$$k(x, y) = (\gamma x^\top y + c_0)^d$$

where:

- $x, y$  are the input vectors
- $d$  is the kernel degree

If  $c_0 = 0$  the kernel is said to be homogeneous.

## Sigmoid kernel

The function `sigmoid_kernel` computes the sigmoid kernel between two vectors. The sigmoid kernel is also known as hyperbolic tangent, or Multilayer Perceptron (because, in the neural network field, it is often used as neuron activation function). It is defined as:

$$k(x, y) = \tanh(\gamma x^\top y + c_0)$$

where:

- $x, y$  are the input vectors
- $\gamma$  is known as slope
- $c_0$  is known as intercept

## RBF kernel

The function `rbf_kernel` computes the radial basis function (RBF) kernel between two vectors. This kernel is defined as:

$$k(x, y) = \exp(-\gamma \|x - y\|^2)$$

where  $x$  and  $y$  are the input vectors. If  $\gamma = \sigma^{-2}$  the kernel is known as the Gaussian kernel of variance  $\sigma^2$ .

## Laplacian kernel

The function `laplacian_kernel` is a variant on the radial basis function kernel defined as:

$$k(x, y) = \exp(-\gamma \|x - y\|_1)$$

where  $x$  and  $y$  are the input vectors and  $\|x - y\|_1$  is the Manhattan distance between the input vectors.

It has proven useful in ML applied to noiseless data. See e.g. [Machine learning for quantum mechanics in a nutshell](#).

## Chi-squared kernel

The chi-squared kernel is a very popular choice for training non-linear SVMs in computer vision applications. It can be computed using `chi2_kernel` and then passed to an `sklearn.svm.SVC` with `kernel="precomputed"`:

```
>>> from sklearn.svm import SVC
>>> from sklearn.metrics.pairwise import chi2_kernel
>>> X = [[0, 1], [1, 0], [.2, .8], [.7, .3]]
>>> y = [0, 1, 0, 1]
>>> K = chi2_kernel(X, gamma=.5)
>>> K
array([[ 1.          ,  0.36...,  0.89...,  0.58...],
       [ 0.36...,  1.          ,  0.51...,  0.83...],
       [ 0.89...,  0.51...,  1.          ,  0.77...],
       [ 0.58...,  0.83...,  0.77...,  1.        ]])

>>> svm = SVC(kernel='precomputed').fit(K, y)
>>> svm.predict(K)
array([0, 1, 0, 1])
```

It can also be directly used as the `kernel` argument:

```
>>> svm = SVC(kernel=chi2_kernel).fit(X, y)
>>> svm.predict(X)
array([0, 1, 0, 1])
```

The chi squared kernel is given by

$$k(x, y) = \exp \left( -\gamma \sum_i \frac{(x[i] - y[i])^2}{x[i] + y[i]} \right)$$

The data is assumed to be non-negative, and is often normalized to have an L1-norm of one. The normalization is rationalized with the connection to the chi squared distance, which is a distance between discrete probability distributions.

The chi squared kernel is most commonly used on histograms (bags) of visual words.

## 3.4.8 Transforming the prediction target (`y`)

### Label binarization

`LabelBinarizer` is a utility class to help create a label indicator matrix from a list of multi-class labels:

```
>>> from sklearn import preprocessing
>>> lb = preprocessing.LabelBinarizer()
>>> lb.fit([1, 2, 6, 4, 2])
LabelBinarizer(neg_label=0, pos_label=1, sparse_output=False)
>>> lb.classes_
```

```
array([1, 2, 4, 6])
>>> lb.transform([1, 6])
array([[1, 0, 0, 0],
       [0, 0, 0, 1]])
```

For multiple labels per instance, use [MultiLabelBinarizer](#):

```
>>> lb = preprocessing.MultiLabelBinarizer()
>>> lb.fit_transform([(1, 2), (3,)])
array([[1, 1, 0],
       [0, 0, 1]])
>>> lb.classes_
array([1, 2, 3])
```

## Label encoding

[LabelEncoder](#) is a utility class to help normalize labels such that they contain only values between 0 and n\_classes-1. This is sometimes useful for writing efficient Cython routines. [LabelEncoder](#) can be used as follows:

```
>>> from sklearn import preprocessing
>>> le = preprocessing.LabelEncoder()
>>> le.fit([1, 2, 2, 6])
LabelEncoder()
>>> le.classes_
array([1, 2, 6])
>>> le.transform([1, 1, 2, 6])
array([0, 0, 1, 2])
>>> le.inverse_transform([0, 0, 1, 2])
array([1, 1, 2, 6])
```

It can also be used to transform non-numerical labels (as long as they are hashable and comparable) to numerical labels:

```
>>> le = preprocessing.LabelEncoder()
>>> le.fit(["paris", "paris", "tokyo", "amsterdam"])
LabelEncoder()
>>> list(le.classes_)
['amsterdam', 'paris', 'tokyo']
>>> le.transform(["tokyo", "tokyo", "paris"])
array([2, 2, 1])
>>> list(le.inverse_transform([2, 2, 1]))
['tokyo', 'tokyo', 'paris']
```

## 3.5 Dataset loading utilities

The `sklearn.datasets` package embeds some small toy datasets as introduced in the [Getting Started](#) section.

To evaluate the impact of the scale of the dataset (`n_samples` and `n_features`) while controlling the statistical properties of the data (typically the correlation and informativeness of the features), it is also possible to generate synthetic data.

This package also features helpers to fetch larger datasets commonly used by the machine learning community to benchmark algorithm on data that comes from the ‘real world’.

### 3.5.1 General dataset API

There are three distinct kinds of dataset interfaces for different types of datasets. The simplest one is the interface for sample images, which is described below in the [Sample images](#) section.

The dataset generation functions and the svmlight loader share a simplistic interface, returning a tuple ( $X$ ,  $y$ ) consisting of a  $n_{samples} * n_{features}$  numpy array  $X$  and an array of length  $n_{samples}$  containing the targets  $y$ .

The toy datasets as well as the ‘real world’ datasets and the datasets fetched from mldata.org have more sophisticated structure. These functions return a dictionary-like object holding at least two items: an array of shape  $n_{samples} * n_{features}$  with key `data` (except for 20newsgroups) and a numpy array of length  $n_{samples}$ , containing the target values, with key `target`.

The datasets also contain a description in `DESCR` and some contain `feature_names` and `target_names`. See the dataset descriptions below for details.

### 3.5.2 Toy datasets

scikit-learn comes with a few small standard datasets that do not require to download any file from some external website.

<code>load_boston([return_X_y])</code>	Load and return the boston house-prices dataset (regression).
<code>load_iris([return_X_y])</code>	Load and return the iris dataset (classification).
<code>load_diabetes([return_X_y])</code>	Load and return the diabetes dataset (regression).
<code>load_digits([n_class, return_X_y])</code>	Load and return the digits dataset (classification).
<code>load_linnerud([return_X_y])</code>	Load and return the linnerud dataset (multivariate regression).
<code>load_wine([return_X_y])</code>	Load and return the wine dataset (classification).
<code>load_breast_cancer([return_X_y])</code>	Load and return the breast cancer wisconsin dataset (classification).

These datasets are useful to quickly illustrate the behavior of the various algorithms implemented in the scikit. They are however often too small to be representative of real world machine learning tasks.

### 3.5.3 Sample images

The scikit also embed a couple of sample JPEG images published under Creative Commons license by their authors. Those image can be useful to test algorithms and pipeline on 2D data.

<code>load_sample_images()</code>	Load sample images for image manipulation.
<code>load_sample_image(image_name)</code>	Load the numpy array of a single sample image

**Warning:** The default coding of images is based on the `uint8` dtype to spare memory. Often machine learning algorithms work best if the input is converted to a floating point representation first. Also, if you plan to use `matplotlib.pyplot.imshow` don't forget to scale to the range 0 - 1 as done in the following example.

**Examples:**

- *Color Quantization using K-Means*

### 3.5.4 Sample generators

In addition, scikit-learn includes various random sample generators that can be used to build artificial datasets of controlled size and complexity.

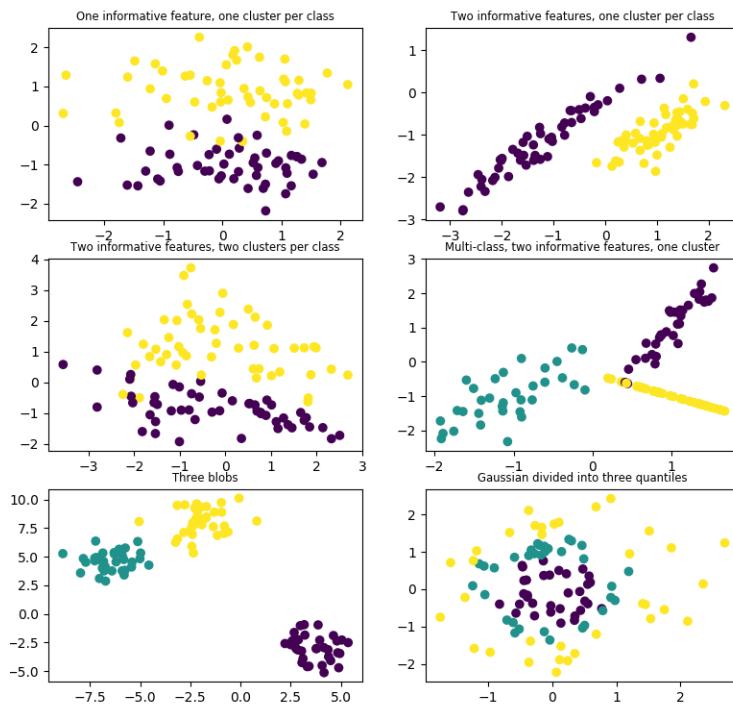

#### Generators for classification and clustering

These generators produce a matrix of features and corresponding discrete targets.

##### Single label

Both `make_blobs` and `make_classification` create multiclass datasets by allocating each class one or more normally-distributed clusters of points. `make_blobs` provides greater control regarding the centers and standard deviations of each cluster, and is used to demonstrate clustering. `make_classification` specialises in introducing noise by way of: correlated, redundant and uninformative features; multiple Gaussian clusters per class; and linear transformations of the feature space.

`make_gaussian_quantiles` divides a single Gaussian cluster into near-equal-size classes separated by concentric hyperspheres. `make_hastie_10_2` generates a similar binary, 10-dimensional problem.

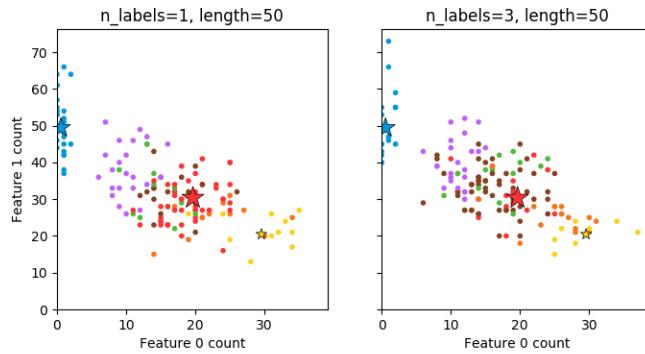

`make_circles` and `make_moons` generate

2d binary classification datasets that are challenging to certain algorithms (e.g. centroid-based clustering or linear classification), including optional Gaussian noise. They are useful for visualisation. `make_gaussian_quantiles` produces Gaussian data with a spherical decision boundary for binary classification.

## Multilabel

`make_multilabel_classification` generates random samples with multiple labels, reflecting a bag of words drawn from a mixture of topics. The number of topics for each document is drawn from a Poisson distribution, and the topics themselves are drawn from a fixed random distribution. Similarly, the number of words is drawn from Poisson, with words drawn from a multinomial, where each topic defines a probability distribution over words. Simplifications with respect to true bag-of-words mixtures include:

- Per-topic word distributions are independently drawn, where in reality all would be affected by a sparse base distribution, and would be correlated.
- For a document generated from multiple topics, all topics are weighted equally in generating its bag of words.
- Documents without labels words at random, rather than from a base distribution.

## Biclustering

---

<code>make_biclusters(shape, n_clusters[, noise, ...])</code>	Generate an array with constant block diagonal structure for biclustering.
<code>make_checkerboard(shape, n_clusters[, ...])</code>	Generate an array with block checkerboard structure for biclustering.

---

## Generators for regression

`make_regression` produces regression targets as an optionally-sparse random linear combination of random features, with noise. Its informative features may be uncorrelated, or low rank (few features account for most of the variance).

Other regression generators generate functions deterministically from randomized features. `make_sparse_uncorrelated` produces a target as a linear combination of four features with fixed coefficients. Others encode explicitly non-linear relations: `make_friedman1` is related by polynomial and sine transforms; `make_friedman2` includes feature multiplication and reciprocation; and `make_friedman3` is similar with an arctan transformation on the target.

## Generators for manifold learning

---

<code>make_s_curve([n_samples, noise, random_state])</code>	Generate an S curve dataset.
<code>make_swiss_roll([n_samples, noise, random_state])</code>	Generate a swiss roll dataset.

---

## Generators for decomposition

---

<code>make_low_rank_matrix([n_samples, ...])</code>	Generate a mostly low rank matrix with bell-shaped singular values
<code>make_sparse_coded_signal(n_samples, ...[, ...])</code>	Generate a signal as a sparse combination of dictionary elements.
<code>make_spd_matrix(n_dim[, random_state])</code>	Generate a random symmetric, positive-definite matrix.
<code>make_sparse_spd_matrix([dim, alpha, ...])</code>	Generate a sparse symmetric definite positive matrix.

---

### 3.5.5 Datasets in svmlight / libsvm format

scikit-learn includes utility functions for loading datasets in the svmlight / libsvm format. In this format, each line takes the form <label> <feature-id>:<feature-value> <feature-id>:<feature-value> ... . This format is especially suitable for sparse datasets. In this module, scipy sparse CSR matrices are used for X and numpy arrays are used for y.

You may load a dataset like as follows:

```
>>> from sklearn.datasets import load_svmlight_file
>>> X_train, y_train = load_svmlight_file("/path/to/train_dataset.txt")
...

```

You may also load two (or more) datasets at once:

```
>>> X_train, y_train, X_test, y_test = load_svmlight_files(
...     "/path/to/train_dataset.txt", "/path/to/test_dataset.txt"))
...

```

In this case, X\_train and X\_test are guaranteed to have the same number of features. Another way to achieve the same result is to fix the number of features:

```
>>> X_test, y_test = load_svmlight_file(
...     "/path/to/test_dataset.txt", n_features=X_train.shape[1])
...

```

Faster API-compatible implementation: <https://github.com/mblondel/svmlight-loader>

### 3.5.6 Loading from external datasets

scikit-learn works on any numeric data stored as numpy arrays or scipy sparse matrices. Other types that are convertible to numeric arrays such as pandas DataFrame are also acceptable.

Here are some recommended ways to load standard columnar data into a format usable by scikit-learn:

- [pandas.io](#) provides tools to read data from common formats including CSV, Excel, JSON and SQL. DataFrames may also be constructed from lists of tuples or dicts. Pandas handles heterogeneous data smoothly and provides tools for manipulation and conversion into a numeric array suitable for scikit-learn.
- [scipy.io](#) specializes in binary formats often used in scientific computing context such as .mat and .arff
- [numpy/routines.io](#) for standard loading of columnar data into numpy arrays
- scikit-learn's `datasets.load_svmlight_file` for the svmlight or libSVM sparse format
- scikit-learn's `datasets.load_files` for directories of text files where the name of each directory is the name of each category and each file inside of each directory corresponds to one sample from that category

For some miscellaneous data such as images, videos, and audio, you may wish to refer to:

- [skimage.io](#) or [Imageio](#) for loading images and videos to numpy arrays
- [scipy.misc.imread](#) (requires the [Pillow](#) package) to load pixel intensities data from various image file formats

- `scipy.io.wavfile.read` for reading WAV files into a numpy array

Categorical (or nominal) features stored as strings (common in pandas DataFrames) will need converting to integers, and integer categorical variables may be best exploited when encoded as one-hot variables (`sklearn.preprocessing.OneHotEncoder`) or similar. See [Preprocessing data](#).

Note: if you manage your own numerical data it is recommended to use an optimized file format such as HDF5 to reduce data load times. Various libraries such as H5Py, PyTables and pandas provides a Python interface for reading and writing data in that format.

## The Olivetti faces dataset

This dataset contains a set of face images taken between April 1992 and April 1994 at AT&T Laboratories Cambridge. The `sklearn.datasets.fetch_olivetti_faces` function is the data fetching / caching function that downloads the data archive from AT&T.

As described on the original website:

There are ten different images of each of 40 distinct subjects. For some subjects, the images were taken at different times, varying the lighting, facial expressions (open / closed eyes, smiling / not smiling) and facial details (glasses / no glasses). All the images were taken against a dark homogeneous background with the subjects in an upright, frontal position (with tolerance for some side movement).

The image is quantized to 256 grey levels and stored as unsigned 8-bit integers; the loader will convert these to floating point values on the interval [0, 1], which are easier to work with for many algorithms.

The “target” for this database is an integer from 0 to 39 indicating the identity of the person pictured; however, with only 10 examples per class, this relatively small dataset is more interesting from an unsupervised or semi-supervised perspective.

The original dataset consisted of 92 x 112, while the version available here consists of 64x64 images.

When using these images, please give credit to AT&T Laboratories Cambridge.

## The 20 newsgroups text dataset

The 20 newsgroups dataset comprises around 18000 newsgroups posts on 20 topics split in two subsets: one for training (or development) and the other one for testing (or for performance evaluation). The split between the train and test set is based upon a messages posted before and after a specific date.

This module contains two loaders. The first one, `sklearn.datasets.fetch_20newsgroups`, returns a list of the raw texts that can be fed to text feature extractors such as `sklearn.feature_extraction.text.CountVectorizer` with custom parameters so as to extract feature vectors. The second one, `sklearn.datasets.fetch_20newsgroups_vectorized`, returns ready-to-use features, i.e., it is not necessary to use a feature extractor.

## Usage

The `sklearn.datasets.fetch_20newsgroups` function is a data fetching / caching functions that downloads the data archive from the original 20 newsgroups website, extracts the archive contents in the `~/scikit_learn_data/20news_home` folder and calls the `sklearn.datasets.load_files` on either the training or testing set folder, or both of them:

```
>>> from sklearn.datasets import fetch_20newsgroups
>>> newsgroups_train = fetch_20newsgroups(subset='train')
```

```
>>> from pprint import pprint
>>> pprint(list(newsgroups_train.target_names))
['alt.atheism',
 'comp.graphics',
 'comp.os.ms-windows.misc',
 'comp.sys.ibm.pc.hardware',
 'comp.sys.mac.hardware',
 'comp.windows.x',
 'misc.forsale',
 'rec.autos',
 'rec.motorcycles',
 'rec.sport.baseball',
 'rec.sport.hockey',
 'sci.crypt',
 'sci.electronics',
 'sci.med',
 'sci.space',
 'soc.religion.christian',
 'talk.politics.guns',
 'talk.politics.mideast',
 'talk.politics.misc',
 'talk.religion.misc']
```

The real data lies in the `filenames` and `target` attributes. The target attribute is the integer index of the category:

```
>>> newsgroups_train.filenames.shape
(11314,)
>>> newsgroups_train.target.shape
(11314,)
>>> newsgroups_train.target[:10]
array([12,  6,  9,  8,  6,  7,  9,  2, 13, 19])
```

It is possible to load only a sub-selection of the categories by passing the list of the categories to load to the `sklearn.datasets.fetch_20newsgroups` function:

```
>>> cats = ['alt.atheism', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train', categories=cats)

>>> list(newsgroups_train.target_names)
['alt.atheism', 'sci.space']
>>> newsgroups_train.filenames.shape
(1073,)
>>> newsgroups_train.target.shape
(1073,)
>>> newsgroups_train.target[:10]
array([1, 1, 1, 0, 1, 0, 0, 1, 1, 1])
```

## Converting text to vectors

In order to feed predictive or clustering models with the text data, one first need to turn the text into vectors of numerical values suitable for statistical analysis. This can be achieved with the utilities of the `sklearn.feature_extraction.text` as demonstrated in the following example that extract TF-IDF vectors of unigram tokens from a subset of 20news:

```
>>> from sklearn.feature_extraction.text import TfidfVectorizer
>>> categories = ['alt.atheism', 'talk.religion.misc',
```

```
...           'comp.graphics', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train',
...                                         categories=categories)
>>> vectorizer = TfidfVectorizer()
>>> vectors = vectorizer.fit_transform(newsgroups_train.data)
>>> vectors.shape
(2034, 34118)
```

The extracted TF-IDF vectors are very sparse, with an average of 159 non-zero components by sample in a more than 30000-dimensional space (less than .5% non-zero features):

```
>>> vectors.nnz / float(vectors.shape[0])
159.01327433628319
```

`sklearn.datasets.fetch_20newsgroups_vectorized` is a function which returns ready-to-use tfidf features instead of file names.

## Filtering text for more realistic training

It is easy for a classifier to overfit on particular things that appear in the 20 Newsgroups data, such as newsgroup headers. Many classifiers achieve very high F-scores, but their results would not generalize to other documents that aren't from this window of time.

For example, let's look at the results of a multinomial Naive Bayes classifier, which is fast to train and achieves a decent F-score:

```
>>> from sklearn.naive_bayes import MultinomialNB
>>> from sklearn import metrics
>>> newsgroups_test = fetch_20newsgroups(subset='test',
...                                         categories=categories)
...
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> clf = MultinomialNB(alpha=.01)
>>> clf.fit(vectors, newsgroups_train.target)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(newsgroups_test.target, pred, average='macro')
0.88213592402729568
```

(The example [Classification of text documents using sparse features](#) shuffles the training and test data, instead of segmenting by time, and in that case multinomial Naive Bayes gets a much higher F-score of 0.88. Are you suspicious yet of what's going on inside this classifier?)

Let's take a look at what the most informative features are:

```
>>> import numpy as np
>>> def show_top10(classifier, vectorizer, categories):
...     feature_names = np.asarray(vectorizer.get_feature_names())
...     for i, category in enumerate(categories):
...         top10 = np.argsort(classifier.coef_[i])[-10:]
...         print("%s: %s" % (category, " ".join(feature_names[top10])))
...
>>> show_top10(clf, vectorizer, newsgroups_train.target_names)
alt.atheism: sgi livesey atheists writes people caltech com god keith edu
comp.graphics: organization thanks files subject com image lines university edu_
↳graphics
sci.space: toronto moon gov com alaska access henry nasa edu space
talk.religion.misc: article writes kent people christian jesus sandvik edu com god
```

You can now see many things that these features have overfit to:

- Almost every group is distinguished by whether headers such as NNTP-Posting-Host: and Distribution: appear more or less often.
- Another significant feature involves whether the sender is affiliated with a university, as indicated either by their headers or their signature.
- The word “article” is a significant feature, based on how often people quote previous posts like this: “In article [article ID], [name] <[e-mail address]> wrote:”
- Other features match the names and e-mail addresses of particular people who were posting at the time.

With such an abundance of clues that distinguish newsgroups, the classifiers barely have to identify topics from text at all, and they all perform at the same high level.

For this reason, the functions that load 20 Newsgroups data provide a parameter called `remove`, telling it what kinds of information to strip out of each file. `remove` should be a tuple containing any subset of ('headers', 'footers', 'quotes'), telling it to remove headers, signature blocks, and quotation blocks respectively.

```
>>> newsgroups_test = fetch_20newsgroups(subset='test',
...                                         remove=('headers', 'footers', 'quotes'),
...                                         categories=categories)
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(pred, newsgroups_test.target, average='macro')
0.77310350681274775
```

This classifier lost over a lot of its F-score, just because we removed metadata that has little to do with topic classification. It loses even more if we also strip this metadata from the training data:

```
>>> newsgroups_train = fetch_20newsgroups(subset='train',
...                                         remove=('headers', 'footers', 'quotes'),
...                                         categories=categories)
>>> vectors = vectorizer.fit_transform(newsgroups_train.data)
>>> clf = MultinomialNB(alpha=.01)
>>> clf.fit(vectors, newsgroups_train.target)
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(newsgroups_test.target, pred, average='macro')
0.76995175184521725
```

Some other classifiers cope better with this harder version of the task. Try running [Sample pipeline for text feature extraction and evaluation](#) with and without the --filter option to compare the results.

## Recommendation

When evaluating text classifiers on the 20 Newsgroups data, you should strip newsgroup-related metadata. In scikit-learn, you can do this by setting `remove=('headers', 'footers', 'quotes')`. The F-score will be lower because it is more realistic.

## Examples

- [Sample pipeline for text feature extraction and evaluation](#)
- [Classification of text documents using sparse features](#)

## Downloading datasets from the mldata.org repository

mldata.org is a public repository for machine learning data, supported by the PASCAL network .

The `sklearn.datasets` package is able to directly download data sets from the repository using the function `sklearn.datasets.fetch_mldata`.

For example, to download the MNIST digit recognition database:

```
>>> from sklearn.datasets import fetch_mldata  
>>> mnist = fetch_mldata('MNIST original', data_home=custom_data_home)
```

The MNIST database contains a total of 70000 examples of handwritten digits of size 28x28 pixels, labeled from 0 to 9:

```
>>> mnist.data.shape  
(70000, 784)  
>>> mnist.target.shape  
(70000,)  
>>> np.unique(mnist.target)  
array([ 0.,  1.,  2.,  3.,  4.,  5.,  6.,  7.,  8.,  9.])
```

After the first download, the dataset is cached locally in the path specified by the `data_home` keyword argument, which defaults to `~/scikit_learn_data/`:

```
>>> os.listdir(os.path.join(custom_data_home, 'mldata'))  
['mnist-original.mat']
```

Data sets in mldata.org do not adhere to a strict naming or formatting convention. `sklearn.datasets.fetch_mldata` is able to make sense of the most common cases, but allows to tailor the defaults to individual datasets:

- The data arrays in mldata.org are most often shaped as `(n_features, n_samples)`. This is the opposite of the scikit-learn convention, so `sklearn.datasets.fetch_mldata` transposes the matrix by default. The `transpose_data` keyword controls this behavior:

```
>>> iris = fetch_mldata('iris', data_home=custom_data_home)  
>>> iris.data.shape  
(150, 4)  
>>> iris = fetch_mldata('iris', transpose_data=False,  
...                      data_home=custom_data_home)  
>>> iris.data.shape  
(4, 150)
```

- For datasets with multiple columns, `sklearn.datasets.fetch_mldata` tries to identify the target and data columns and rename them to `target` and `data`. This is done by looking for arrays named `label` and `data` in the dataset, and failing that by choosing the first array to be `target` and the second to be `data`. This behavior can be changed with the `target_name` and `data_name` keywords, setting them to a specific name or index number (the name and order of the columns in the datasets can be found at its mldata.org under the tab “Data”):

```
>>> iris2 = fetch_mldata('datasets-UCI iris', target_name=1, data_name=0,  
...                      data_home=custom_data_home)  
>>> iris3 = fetch_mldata('datasets-UCI iris', target_name='class',  
...                      data_name='double0', data_home=custom_data_home)
```

## The Labeled Faces in the Wild face recognition dataset

This dataset is a collection of JPEG pictures of famous people collected over the internet, all details are available on the official website:

<http://vis-www.cs.umass.edu/lfw/>

Each picture is centered on a single face. The typical task is called Face Verification: given a pair of two pictures, a binary classifier must predict whether the two images are from the same person.

An alternative task, Face Recognition or Face Identification is: given the picture of the face of an unknown person, identify the name of the person by referring to a gallery of previously seen pictures of identified persons.

Both Face Verification and Face Recognition are tasks that are typically performed on the output of a model trained to perform Face Detection. The most popular model for Face Detection is called Viola-Jones and is implemented in the OpenCV library. The LFW faces were extracted by this face detector from various online websites.

## Usage

scikit-learn provides two loaders that will automatically download, cache, parse the metadata files, decode the jpeg and convert the interesting slices into memmapped numpy arrays. This dataset size is more than 200 MB. The first load typically takes more than a couple of minutes to fully decode the relevant part of the JPEG files into numpy arrays. If the dataset has been loaded once, the following times the loading times less than 200ms by using a memmapped version memoized on the disk in the `~/scikit_learn_data/lfw_home/` folder using `joblib`.

The first loader is used for the Face Identification task: a multi-class classification task (hence supervised learning):

```
>>> from sklearn.datasets import fetch_lfw_people
>>> lfw_people = fetch_lfw_people(min_faces_per_person=70, resize=0.4)

>>> for name in lfw_people.target_names:
...     print(name)
...
Ariel Sharon
Colin Powell
Donald Rumsfeld
George W Bush
Gerhard Schroeder
Hugo Chavez
Tony Blair
```

The default slice is a rectangular shape around the face, removing most of the background:

```
>>> lfw_people.data.dtype
dtype('float32')

>>> lfw_people.data.shape
(1288, 1850)

>>> lfw_people.images.shape
(1288, 50, 37)
```

Each of the 1140 faces is assigned to a single person id in the `target` array:

```
>>> lfw_people.target.shape
(1288,)
```

```
>>> list(lfw_people.target[:10])
[5, 6, 3, 1, 0, 1, 3, 4, 3, 0]
```

The second loader is typically used for the face verification task: each sample is a pair of two picture belonging or not to the same person:

```
>>> from sklearn.datasets import fetch_lfw_pairs
>>> lfw_pairs_train = fetch_lfw_pairs(subset='train')

>>> list(lfw_pairs_train.target_names)
['Different persons', 'Same person']

>>> lfw_pairs_train.pairs.shape
(2200, 2, 62, 47)

>>> lfw_pairs_train.data.shape
(2200, 5828)

>>> lfw_pairs_train.target.shape
(2200,)
```

Both for the `sklearn.datasets.fetch_lfw_people` and `sklearn.datasets.fetch_lfw_pairs` function it is possible to get an additional dimension with the RGB color channels by passing `color=True`, in that case the shape will be `(2200, 2, 62, 47, 3)`.

The `sklearn.datasets.fetch_lfw_pairs` datasets is subdivided into 3 subsets: the development `train` set, the development `test` set and an evaluation `10_folds` set meant to compute performance metrics using a 10-folds cross validation scheme.

## Examples

[sphx\\_glr\\_auto\\_examples\\_applications\\_face\\_recognition.py](#)

## Forest covtypes

The samples in this dataset correspond to 30×30m patches of forest in the US, collected for the task of predicting each patch's cover type, i.e. the dominant species of tree. There are seven covtypes, making this a multiclass classification problem. Each sample has 54 features, described on the [dataset's homepage](#). Some of the features are boolean indicators, while others are discrete or continuous measurements.

`sklearn.datasets.fetch_covtype` will load the covtype dataset; it returns a dictionary-like object with the feature matrix in the `data` member and the target values in `target`. The dataset will be downloaded from the web if necessary.

## RCV1 dataset

Reuters Corpus Volume I (RCV1) is an archive of over 800,000 manually categorized newswire stories made available by Reuters, Ltd. for research purposes. The dataset is extensively described in<sup>1</sup>.

`sklearn.datasets.fetch_rcv1` will load the following version: RCV1-v2, vectors, full sets, topics multilabels:

```
>>> from sklearn.datasets import fetch_rcv1
>>> rcv1 = fetch_rcv1()
```

It returns a dictionary-like object, with the following attributes:

`data`: The feature matrix is a scipy CSR sparse matrix, with 804414 samples and 47236 features. Non-zero values contains cosine-normalized, log TF-IDF vectors. A nearly chronological split is proposed in<sup>1</sup>: The first 23149 samples are the training set. The last 781265 samples are the testing set. This follows the official LYRL2004 chronological split. The array has 0.16% of non zero values:

```
>>> rcv1.data.shape
(804414, 47236)
```

`target`: The target values are stored in a scipy CSR sparse matrix, with 804414 samples and 103 categories. Each sample has a value of 1 in its categories, and 0 in others. The array has 3.15% of non zero values:

```
>>> rcv1.target.shape
(804414, 103)
```

`sample_id`: Each sample can be identified by its ID, ranging (with gaps) from 2286 to 810596:

```
>>> rcv1.sample_id[:3]
array([2286, 2287, 2288], dtype=uint32)
```

`target_names`: The target values are the topics of each sample. Each sample belongs to at least one topic, and to up to 17 topics. There are 103 topics, each represented by a string. Their corpus frequencies span five orders of magnitude, from 5 occurrences for ‘GMIL’, to 381327 for ‘CCAT’:

```
>>> rcv1.target_names[:3].tolist()
['E11', 'ECAT', 'M11']
```

The dataset will be downloaded from the `rcv1` homepage if necessary. The compressed size is about 656 MB.

## References

### 3.5.7 The Olivetti faces dataset

This dataset contains a set of face images taken between April 1992 and April 1994 at AT&T Laboratories Cambridge. The `sklearn.datasets.fetch_olivetti_faces` function is the data fetching / caching function that downloads the data archive from AT&T.

As described on the original website:

<sup>1</sup> Lewis, D. D., Yang, Y., Rose, T. G., & Li, F. (2004). RCV1: A new benchmark collection for text categorization research. *The Journal of Machine Learning Research*, 5, 361-397.

There are ten different images of each of 40 distinct subjects. For some subjects, the images were taken at different times, varying the lighting, facial expressions (open / closed eyes, smiling / not smiling) and facial details (glasses / no glasses). All the images were taken against a dark homogeneous background with the subjects in an upright, frontal position (with tolerance for some side movement).

The image is quantized to 256 grey levels and stored as unsigned 8-bit integers; the loader will convert these to floating point values on the interval [0, 1], which are easier to work with for many algorithms.

The “target” for this database is an integer from 0 to 39 indicating the identity of the person pictured; however, with only 10 examples per class, this relatively small dataset is more interesting from an unsupervised or semi-supervised perspective.

The original dataset consisted of 92 x 112, while the version available here consists of 64x64 images.

When using these images, please give credit to AT&T Laboratories Cambridge.

### 3.5.8 The 20 newsgroups text dataset

The 20 newsgroups dataset comprises around 18000 newsgroups posts on 20 topics split in two subsets: one for training (or development) and the other one for testing (or for performance evaluation). The split between the train and test set is based upon a messages posted before and after a specific date.

This module contains two loaders. The first one, `sklearn.datasets.fetch_20newsgroups`, returns a list of the raw texts that can be fed to text feature extractors such as `sklearn.feature_extraction.text.CountVectorizer` with custom parameters so as to extract feature vectors. The second one, `sklearn.datasets.fetch_20newsgroups_vectorized`, returns ready-to-use features, i.e., it is not necessary to use a feature extractor.

#### Usage

The `sklearn.datasets.fetch_20newsgroups` function is a data fetching / caching functions that downloads the data archive from the original 20 newsgroups website, extracts the archive contents in the `~/scikit_learn_data/20news_home` folder and calls the `sklearn.datasets.load_files` on either the training or testing set folder, or both of them:

```
>>> from sklearn.datasets import fetch_20newsgroups
>>> newsgroups_train = fetch_20newsgroups(subset='train')

>>> from pprint import pprint
>>> pprint(list(newsgroups_train.target_names))
['alt.atheism',
 'comp.graphics',
 'comp.os.ms-windows.misc',
 'comp.sys.ibm.pc.hardware',
 'comp.sys.mac.hardware',
 'comp.windows.x',
 'misc.forsale',
 'rec.autos',
 'rec.motorcycles',
 'rec.sport.baseball',
 'rec.sport.hockey',
 'sci.crypt',
 'sci.electronics',
 'sci.med',
 'sci.space',
 'soc.religion.christian',
 'talk.politics.guns',
```

```
'talk.politics.mideast',
'talk.politics.misc',
'talk.religion.misc']
```

The real data lies in the `filenames` and `target` attributes. The target attribute is the integer index of the category:

```
>>> newsgroups_train.filenames.shape
(11314,)
>>> newsgroups_train.target.shape
(11314,)
>>> newsgroups_train.target[:10]
array([12,  6,  9,  8,  6,  7,  9,  2, 13, 19])
```

It is possible to load only a sub-selection of the categories by passing the list of the categories to load to the `sklearn.datasets.fetch_20newsgroups` function:

```
>>> cats = ['alt.atheism', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train', categories=cats)

>>> list(newsgroups_train.target_names)
['alt.atheism', 'sci.space']
>>> newsgroups_train.filenames.shape
(1073,)
>>> newsgroups_train.target.shape
(1073,)
>>> newsgroups_train.target[:10]
array([1, 1, 1, 0, 1, 0, 0, 1, 1, 1])
```

## Converting text to vectors

In order to feed predictive or clustering models with the text data, one first need to turn the text into vectors of numerical values suitable for statistical analysis. This can be achieved with the utilities of the `sklearn.feature_extraction.text` as demonstrated in the following example that extract TF-IDF vectors of unigram tokens from a subset of 20news:

```
>>> from sklearn.feature_extraction.text import TfidfVectorizer
>>> categories = ['alt.atheism', 'talk.religion.misc',
...                 'comp.graphics', 'sci.space']
>>> newsgroups_train = fetch_20newsgroups(subset='train',
...                                         categories=categories)
>>> vectorizer = TfidfVectorizer()
>>> vectors = vectorizer.fit_transform(newsgroups_train.data)
>>> vectors.shape
(2034, 34118)
```

The extracted TF-IDF vectors are very sparse, with an average of 159 non-zero components by sample in a more than 30000-dimensional space (less than .5% non-zero features):

```
>>> vectors.nnz / float(vectors.shape[0])
159.01327433628319
```

`sklearn.datasets.fetch_20newsgroups_vectorized` is a function which returns ready-to-use tfidf features instead of file names.

## Filtering text for more realistic training

It is easy for a classifier to overfit on particular things that appear in the 20 Newsgroups data, such as newsgroup headers. Many classifiers achieve very high F-scores, but their results would not generalize to other documents that aren't from this window of time.

For example, let's look at the results of a multinomial Naive Bayes classifier, which is fast to train and achieves a decent F-score:

```
>>> from sklearn.naive_bayes import MultinomialNB
>>> from sklearn import metrics
>>> newsgroups_test = fetch_20newsgroups(subset='test',
...                                         categories=categories)
>>> vectorizer.transform(newsgroups_test.data)
>>> clf = MultinomialNB(alpha=.01)
>>> clf.fit(vectors, newsgroups_train.target)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(newsgroups_test.target, pred, average='macro')
0.88213592402729568
```

(The example [Classification of text documents using sparse features](#) shuffles the training and test data, instead of segmenting by time, and in that case multinomial Naive Bayes gets a much higher F-score of 0.88. Are you suspicious yet of what's going on inside this classifier?)

Let's take a look at what the most informative features are:

```
>>> import numpy as np
>>> def show_top10(classifier, vectorizer, categories):
...     feature_names = np.asarray(vectorizer.get_feature_names())
...     for i, category in enumerate(categories):
...         top10 = np.argsort(classifier.coef_[i])[-10:]
...         print("%s: %s" % (category, " ".join(feature_names[top10])))
...
>>> show_top10(clf, vectorizer, newsgroups_train.target_names)
alt.atheism: sgi livesey atheists writes people caltech com god keith edu
comp.graphics: organization thanks files subject com image lines university edu_
↳graphics
sci.space: toronto moon gov com alaska access henry nasa edu space
talk.religion.misc: article writes kent people christian jesus sandvik edu com god
```

You can now see many things that these features have overfit to:

- Almost every group is distinguished by whether headers such as NNTP-Posting-Host: and Distribution: appear more or less often.
- Another significant feature involves whether the sender is affiliated with a university, as indicated either by their headers or their signature.
- The word “article” is a significant feature, based on how often people quote previous posts like this: “In article [article ID], [name] <[e-mail address]> wrote:”
- Other features match the names and e-mail addresses of particular people who were posting at the time.

With such an abundance of clues that distinguish newsgroups, the classifiers barely have to identify topics from text at all, and they all perform at the same high level.

For this reason, the functions that load 20 Newsgroups data provide a parameter called `remove`, telling it what kinds of information to strip out of each file. `remove` should be a tuple containing any subset of ('headers', 'footers', 'quotes'), telling it to remove headers, signature blocks, and quotation blocks respectively.

```
>>> newsgroups_test = fetch_20newsgroups(subset='test',
...                                         remove=('headers', 'footers', 'quotes'),
...                                         categories=categories)
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(pred, newsgroups_test.target, average='macro')
0.77310350681274775
```

This classifier lost over a lot of its F-score, just because we removed metadata that has little to do with topic classification. It loses even more if we also strip this metadata from the training data:

```
>>> newsgroups_train = fetch_20newsgroups(subset='train',
...                                         remove=('headers', 'footers', 'quotes'),
...                                         categories=categories)
>>> vectors = vectorizer.fit_transform(newsgroups_train.data)
>>> clf = MultinomialNB(alpha=.01)
>>> clf.fit(vectors, newsgroups_train.target)
>>> vectors_test = vectorizer.transform(newsgroups_test.data)
>>> pred = clf.predict(vectors_test)
>>> metrics.f1_score(newsgroups_test.target, pred, average='macro')
0.76995175184521725
```

Some other classifiers cope better with this harder version of the task. Try running [Sample pipeline for text feature extraction and evaluation](#) with and without the --filter option to compare the results.

## Recommendation

When evaluating text classifiers on the 20 Newsgroups data, you should strip newsgroup-related metadata. In scikit-learn, you can do this by setting `remove=('headers', 'footers', 'quotes')`. The F-score will be lower because it is more realistic.

### 3.5.9 Downloading datasets from the mldata.org repository

[mldata.org](#) is a public repository for machine learning data, supported by the PASCAL network .

The `sklearn.datasets` package is able to directly download data sets from the repository using the function `sklearn.datasets.fetch_mldata`.

For example, to download the MNIST digit recognition database:

```
>>> from sklearn.datasets import fetch_mldata
>>> mnist = fetch_mldata('MNIST original', data_home=custom_data_home)
```

The MNIST database contains a total of 70000 examples of handwritten digits of size 28x28 pixels, labeled from 0 to 9:

```
>>> mnist.data.shape  
(70000, 784)  
>>> mnist.target.shape  
(70000,)  
>>> np.unique(mnist.target)  
array([ 0.,  1.,  2.,  3.,  4.,  5.,  6.,  7.,  8.,  9.])
```

After the first download, the dataset is cached locally in the path specified by the `data_home` keyword argument, which defaults to `~/scikit_learn_data/`:

```
>>> os.listdir(os.path.join(custom_data_home, 'mldata'))  
['mnist-original.mat']
```

Data sets in [mldata.org](#) do not adhere to a strict naming or formatting convention. `sklearn.datasets.fetch_mldata` is able to make sense of the most common cases, but allows to tailor the defaults to individual datasets:

- The data arrays in [mldata.org](#) are most often shaped as `(n_features, n_samples)`. This is the opposite of the scikit-learn convention, so `sklearn.datasets.fetch_mldata` transposes the matrix by default. The `transpose_data` keyword controls this behavior:

```
>>> iris = fetch_mldata('iris', data_home=custom_data_home)  
>>> iris.data.shape  
(150, 4)  
>>> iris = fetch_mldata('iris', transpose_data=False,  
...                      data_home=custom_data_home)  
>>> iris.data.shape  
(4, 150)
```

- For datasets with multiple columns, `sklearn.datasets.fetch_mldata` tries to identify the target and data columns and rename them to `target` and `data`. This is done by looking for arrays named `label` and `data` in the dataset, and failing that by choosing the first array to be `target` and the second to be `data`. This behavior can be changed with the `target_name` and `data_name` keywords, setting them to a specific name or index number (the name and order of the columns in the datasets can be found at its [mldata.org](#) under the tab “Data”):

```
>>> iris2 = fetch_mldata('datasets-UCI iris', target_name=1, data_name=0,  
...                      data_home=custom_data_home)  
>>> iris3 = fetch_mldata('datasets-UCI iris', target_name='class',  
...                      data_name='double0', data_home=custom_data_home)
```

### 3.5.10 The Labeled Faces in the Wild face recognition dataset

This dataset is a collection of JPEG pictures of famous people collected over the internet, all details are available on the official website:

<http://vis-www.cs.umass.edu/lfw/>

Each picture is centered on a single face. The typical task is called Face Verification: given a pair of two pictures, a binary classifier must predict whether the two images are from the same person.

An alternative task, Face Recognition or Face Identification is: given the picture of the face of an unknown person, identify the name of the person by referring to a gallery of previously seen pictures of identified persons.

Both Face Verification and Face Recognition are tasks that are typically performed on the output of a model trained to perform Face Detection. The most popular model for Face Detection is called Viola-Jones and is implemented in the OpenCV library. The LFW faces were extracted by this face detector from various online websites.

## Usage

scikit-learn provides two loaders that will automatically download, cache, parse the metadata files, decode the jpeg and convert the interesting slices into memmapped numpy arrays. This dataset size is more than 200 MB. The first load typically takes more than a couple of minutes to fully decode the relevant part of the JPEG files into numpy arrays. If the dataset has been loaded once, the following times the loading times less than 200ms by using a memmapped version memoized on the disk in the `~/scikit_learn_data/lfw_home/` folder using `joblib`.

The first loader is used for the Face Identification task: a multi-class classification task (hence supervised learning):

```
>>> from sklearn.datasets import fetch_lfw_people
>>> lfw_people = fetch_lfw_people(min_faces_per_person=70, resize=0.4)

>>> for name in lfw_people.target_names:
...     print(name)
...
Ariel Sharon
Colin Powell
Donald Rumsfeld
George W Bush
Gerhard Schroeder
Hugo Chavez
Tony Blair
```

The default slice is a rectangular shape around the face, removing most of the background:

```
>>> lfw_people.data.dtype
dtype('float32')

>>> lfw_people.data.shape
(1288, 1850)

>>> lfw_people.images.shape
(1288, 50, 37)
```

Each of the 1140 faces is assigned to a single person id in the `target` array:

```
>>> lfw_people.target.shape
(1288,)

>>> list(lfw_people.target[:10])
[5, 6, 3, 1, 0, 1, 3, 4, 3, 0]
```

The second loader is typically used for the face verification task: each sample is a pair of two picture belonging or not to the same person:

```
>>> from sklearn.datasets import fetch_lfw_pairs
>>> lfw_pairs_train = fetch_lfw_pairs(subset='train')

>>> list(lfw_pairs_train.target_names)
['Different persons', 'Same person']

>>> lfw_pairs_train.pairs.shape
(2200, 2, 62, 47)

>>> lfw_pairs_train.data.shape
(2200, 5828)
```

```
>>> lfw_pairs_train.target.shape  
(2200,)
```

Both for the `sklearn.datasets.fetch_lfw_people` and `sklearn.datasets.fetch_lfw_pairs` function it is possible to get an additional dimension with the RGB color channels by passing `color=True`, in that case the shape will be `(2200, 2, 62, 47, 3)`.

The `sklearn.datasets.fetch_lfw_pairs` datasets is subdivided into 3 subsets: the development `train` set, the development `test` set and an evaluation `10_folds` set meant to compute performance metrics using a 10-folds cross validation scheme.

## Examples

`sphx_glr_auto_examples_applications_face_recognition.py`

### 3.5.11 Forest covtypes

The samples in this dataset correspond to 30×30m patches of forest in the US, collected for the task of predicting each patch's cover type, i.e. the dominant species of tree. There are seven covtypes, making this a multiclass classification problem. Each sample has 54 features, described on the [dataset's homepage](#). Some of the features are boolean indicators, while others are discrete or continuous measurements.

`sklearn.datasets.fetch_covtype` will load the covtype dataset; it returns a dictionary-like object with the feature matrix in the `data` member and the target values in `target`. The dataset will be downloaded from the web if necessary.

### 3.5.12 RCV1 dataset

Reuters Corpus Volume I (RCV1) is an archive of over 800,000 manually categorized newswire stories made available by Reuters, Ltd. for research purposes. The dataset is extensively described in<sup>1</sup>.

`sklearn.datasets.fetch_rcv1` will load the following version: RCV1-v2, vectors, full sets, topics multilabels:

```
>>> from sklearn.datasets import fetch_rcv1  
>>> rcv1 = fetch_rcv1()
```

It returns a dictionary-like object, with the following attributes:

`data`: The feature matrix is a scipy CSR sparse matrix, with 804414 samples and 47236 features. Non-zero values contains cosine-normalized, log TF-IDF vectors. A nearly chronological split is proposed in<sup>1</sup>: The first 23149 samples are the training set. The last 781265 samples are the testing set. This follows the official LYRL2004 chronological split. The array has 0.16% of non zero values:

<sup>1</sup> Lewis, D. D., Yang, Y., Rose, T. G., & Li, F. (2004). RCV1: A new benchmark collection for text categorization research. *The Journal of Machine Learning Research*, 5, 361-397.

```
>>> rcv1.data.shape
(804414, 47236)
```

`target`: The target values are stored in a scipy CSR sparse matrix, with 804414 samples and 103 categories. Each sample has a value of 1 in its categories, and 0 in others. The array has 3.15% of non zero values:

```
>>> rcv1.target.shape
(804414, 103)
```

`sample_id`: Each sample can be identified by its ID, ranging (with gaps) from 2286 to 810596:

```
>>> rcv1.sample_id[:3]
array([2286, 2287, 2288], dtype=uint32)
```

`target_names`: The target values are the topics of each sample. Each sample belongs to at least one topic, and to up to 17 topics. There are 103 topics, each represented by a string. Their corpus frequencies span five orders of magnitude, from 5 occurrences for ‘GMIL’, to 381327 for ‘CCAT’:

```
>>> rcv1.target_names[:3].tolist()
['E11', 'ECAT', 'M11']
```

The dataset will be downloaded from the [rcv1](#) homepage if necessary. The compressed size is about 656 MB.

### 3.5.13 Boston House Prices dataset

#### Notes

Data Set Characteristics:

**Number of Instances** 506

**Number of Attributes** 13 numeric/categorical predictive

:Median Value (attribute 14) is usually the target

#### Attribute Information (in order)

- CRIM per capita crime rate by town
- ZN proportion of residential land zoned for lots over 25,000 sq.ft.
- INDUS proportion of non-retail business acres per town
- CHAS Charles River dummy variable (= 1 if tract bounds river; 0 otherwise)
- NOX nitric oxides concentration (parts per 10 million)
- RM average number of rooms per dwelling
- AGE proportion of owner-occupied units built prior to 1940
- DIS weighted distances to five Boston employment centres
- RAD index of accessibility to radial highways
- TAX full-value property-tax rate per \$10,000

- PTRATIO pupil-teacher ratio by town
- B  $1000(B_k - 0.63)^2$  where  $B_k$  is the proportion of blacks by town
- LSTAT % lower status of the population
- MEDV Median value of owner-occupied homes in \$1000's

**Missing Attribute Values** None

**Creator** Harrison, D. and Rubinfeld, D.L.

This is a copy of UCI ML housing dataset. <http://archive.ics.uci.edu/ml/datasets/Housing>

This dataset was taken from the StatLib library which is maintained at Carnegie Mellon University.

The Boston house-price data of Harrison, D. and Rubinfeld, D.L. ‘Hedonic prices and the demand for clean air’, J. Environ. Economics & Management, vol.5, 81-102, 1978. Used in Belsley, Kuh & Welsch, ‘Regression diagnostics ...’, Wiley, 1980. N.B. Various transformations are used in the table on pages 244-261 of the latter.

The Boston house-price data has been used in many machine learning papers that address regression problems.

## 3.5.14 Breast Cancer Wisconsin (Diagnostic) Database

### Notes

#### Data Set Characteristics:

**Number of Instances** 569

**Number of Attributes** 30 numeric, predictive attributes and the class

#### Attribute Information

- radius (mean of distances from center to points on the perimeter)
- texture (standard deviation of gray-scale values)
- perimeter
- area
- smoothness (local variation in radius lengths)
- compactness ( $\text{perimeter}^2 / \text{area} - 1.0$ )
- concavity (severity of concave portions of the contour)
- concave points (number of concave portions of the contour)
- symmetry
- fractal dimension (“coastline approximation” - 1)

The mean, standard error, and “worst” or largest (mean of the three largest values) of these features were computed for each image, resulting in 30 features. For instance, field 3 is Mean Radius, field 13 is Radius SE, field 23 is Worst Radius.

- **class:**
  - WDBC-Malignant
  - WDBC-Benign

### Summary Statistics

radius (mean):	6.981	28.11
texture (mean):	9.71	39.28
perimeter (mean):	43.79	188.5
area (mean):	143.5	2501.0
smoothness (mean):	0.053	0.163
compactness (mean):	0.019	0.345
concavity (mean):	0.0	0.427
concave points (mean):	0.0	0.201
symmetry (mean):	0.106	0.304
fractal dimension (mean):	0.05	0.097
radius (standard error):	0.112	2.873
texture (standard error):	0.36	4.885
perimeter (standard error):	0.757	21.98
area (standard error):	6.802	542.2
smoothness (standard error):	0.002	0.031
compactness (standard error):	0.002	0.135
concavity (standard error):	0.0	0.396
concave points (standard error):	0.0	0.053
symmetry (standard error):	0.008	0.079
fractal dimension (standard error):	0.001	0.03
radius (worst):	7.93	36.04
texture (worst):	12.02	49.54
perimeter (worst):	50.41	251.2
area (worst):	185.2	4254.0
smoothness (worst):	0.071	0.223
compactness (worst):	0.027	1.058
concavity (worst):	0.0	1.252
concave points (worst):	0.0	0.291
symmetry (worst):	0.156	0.664
fractal dimension (worst):	0.055	0.208

**Donor** Nick Street

**Date** November, 1995

This is a copy of UCI ML Breast Cancer Wisconsin (Diagnostic) datasets. <https://goo.gl/U2Uwz>

Features are computed from a digitized image of a fine needle aspirate (FNA) of a breast mass. They describe characteristics of the cell nuclei present in the image.

Separating plane described above was obtained using Multisurface Method-Tree (MSM-T) [K. P. Bennett, “Decision Tree Construction Via Linear Programming.” Proceedings of the 4th Midwest Artificial Intelligence and Cognitive Science Society, pp. 97-101, 1992], a classification method which uses linear programming to construct a decision tree. Relevant features were selected using an exhaustive search in the space of 1-4 features and 1-3 separating planes.

The actual linear program used to obtain the separating plane in the 3-dimensional space is that described in: [K. P. Bennett and O. L. Mangasarian: “Robust Linear Programming Discrimination of Two Linearly Inseparable Sets”, Optimization Methods and Software 1, 1992, 23-34].

This database is also available through the UW CS ftp server:

```
ftp ftp.cs.wisc.edu cd math-prog/cpo-dataset/machine-learn/WDBC/
```

### 3.5.15 Diabetes dataset

#### Notes

Ten baseline variables, age, sex, body mass index, average blood pressure, and six blood serum measurements were obtained for each of  $n = 442$  diabetes patients, as well as the response of interest, a quantitative measure of disease progression one year after baseline.

Data Set Characteristics:

**Number of Instances** 442

**Number of Attributes** First 10 columns are numeric predictive values

**Target** Column 11 is a quantitative measure of disease progression one year after baseline

#### Attributes

**Age**

**Sex**

**Body mass index**

**Average blood pressure**

**S1**

**S2**

**S3**

**S4**

**S5**

**S6**

Note: Each of these 10 feature variables have been mean centered and scaled by the standard deviation times  $n\_samples$  (i.e. the sum of squares of each column totals 1).

### 3.5.16 Optical Recognition of Handwritten Digits Data Set

#### Notes

##### Data Set Characteristics:

**Number of Instances** 5620

**Number of Attributes** 64

**Attribute Information** 8x8 image of integer pixels in the range 0..16.

**Missing Attribute Values** None

**Creator**

5. Alpaydin (alpaydin '@' boun.edu.tr)

**Date** July; 1998

This is a copy of the test set of the UCI ML hand-written digits datasets <http://archive.ics.uci.edu/ml/datasets/Optical+Recognition+of+Handwritten+Digits>

The data set contains images of hand-written digits: 10 classes where each class refers to a digit.

Preprocessing programs made available by NIST were used to extract normalized bitmaps of handwritten digits from a preprinted form. From a total of 43 people, 30 contributed to the training set and different 13 to the test set. 32x32 bitmaps are divided into nonoverlapping blocks of 4x4 and the number of on pixels are counted in each block. This generates an input matrix of 8x8 where each element is an integer in the range 0..16. This reduces dimensionality and gives invariance to small distortions.

For info on NIST preprocessing routines, see M. D. Garris, J. L. Blue, G. T. Candela, D. L. Dimmick, J. Geist, P. J. Grother, S. A. Janet, and C. L. Wilson, NIST Form-Based Handprint Recognition System, NISTIR 5469, 1994.

### 3.5.17 Iris Plants Database

#### Notes

##### Data Set Characteristics:

**Number of Instances** 150 (50 in each of three classes)

**Number of Attributes** 4 numeric, predictive attributes and the class

##### Attribute Information

- sepal length in cm

- sepal width in cm

- petal length in cm

- petal width in cm

- **class:**

  - Iris-Setosa

  - Iris-Versicolour

  - Iris-Virginica

##### Summary Statistics

sepal length:	4.3	7.9	5.84	0.83	0.7826
sepal width:	2.0	4.4	3.05	0.43	-0.4194
petal length:	1.0	6.9	3.76	1.76	0.9490 (high!)
petal width:	0.1	2.5	1.20	0.76	0.9565 (high!)

**Missing Attribute Values** None

**Class Distribution** 33.3% for each of 3 classes.

**Creator** R.A. Fisher

**Donor** Michael Marshall ([MARSHALL%PLU@io.arc.nasa.gov](mailto:MARSHALL%PLU@io.arc.nasa.gov))

**Date** July, 1988

This is a copy of UCI ML iris datasets. <http://archive.ics.uci.edu/ml/datasets/Iris>

The famous Iris database, first used by Sir R.A Fisher

This is perhaps the best known database to be found in the pattern recognition literature. Fisher's paper is a classic in the field and is referenced frequently to this day. (See Duda & Hart, for example.) The data set contains 3 classes of 50 instances each, where each class refers to a type of iris plant. One class is linearly separable from the other 2; the latter are NOT linearly separable from each other.

### 3.5.18 Linnerud dataset

#### Notes

##### Data Set Characteristics:

**Number of Instances** 20

**Number of Attributes** 3

**Missing Attribute Values** None

The Linnerud dataset contains two small datasets:

- **exercise**: A list containing the following components: exercise data with 20 observations on 3 exercise variables: Weight, Waist and Pulse.
- **physiological**: Data frame with 20 observations on 3 physiological variables: Chins, Situps and Jumps.

## 3.6 Strategies to scale computationally: bigger data

For some applications the amount of examples, features (or both) and/or the speed at which they need to be processed are challenging for traditional approaches. In these cases scikit-learn has a number of options you can consider to make your system scale.

### 3.6.1 Scaling with instances using out-of-core learning

Out-of-core (or “external memory”) learning is a technique used to learn from data that cannot fit in a computer’s main memory (RAM).

Here is a sketch of a system designed to achieve this goal:

1. a way to stream instances
2. a way to extract features from instances
3. an incremental algorithm

## Streaming instances

Basically, 1. may be a reader that yields instances from files on a hard drive, a database, from a network stream etc. However, details on how to achieve this are beyond the scope of this documentation.

## Extracting features

2. could be any relevant way to extract features among the different *feature extraction* methods supported by scikit-learn. However, when working with data that needs vectorization and where the set of features or values is not known in advance one should take explicit care. A good example is text classification where unknown terms are likely to be found during training. It is possible to use a statefull vectorizer if making multiple passes over the data is reasonable from an application point of view. Otherwise, one can turn up the difficulty by using a stateless feature extractor. Currently the preferred way to do this is to use the so-called *hashing trick* as implemented by `sklearn.feature_extraction.FeatureHasher` for datasets with categorical variables represented as list of Python dicts or `sklearn.feature_extraction.text.HashingVectorizer` for text documents.

## Incremental learning

Finally, for 3. we have a number of options inside scikit-learn. Although all algorithms cannot learn incrementally (i.e. without seeing all the instances at once), all estimators implementing the `partial_fit` API are candidates. Actually, the ability to learn incrementally from a mini-batch of instances (sometimes called “online learning”) is key to out-of-core learning as it guarantees that at any given time there will be only a small amount of instances in the main memory. Choosing a good size for the mini-batch that balances relevancy and memory footprint could involve some tuning<sup>1</sup>.

Here is a list of incremental estimators for different tasks:

- Classification

- `sklearn.naive_bayes.MultinomialNB`
- `sklearn.naive_bayes.BernoulliNB`
- `sklearn.linear_model.Perceptron`
- `sklearn.linear_model.SGDClassifier`
- `sklearn.linear_model.PassiveAggressiveClassifier`
- `sklearn.neural_network.MLPClassifier`

- Regression

- `sklearn.linear_model.SGDRegressor`
- `sklearn.linear_model.PassiveAggressiveRegressor`
- `sklearn.neural_network.MLPRegressor`

- Clustering

- `sklearn.cluster.MiniBatchKMeans`
- `sklearn.cluster.Birch`

- Decomposition / feature Extraction

- `sklearn.decomposition.MiniBatchDictionaryLearning`

---

<sup>1</sup> Depending on the algorithm the mini-batch size can influence results or not. SGD\*, PassiveAggressive\*, and discrete NaiveBayes are truly online and are not affected by batch size. Conversely, MiniBatchKMeans convergence rate is affected by the batch size. Also, its memory footprint can vary dramatically with batch size.

- `sklearn.decomposition.IncrementalPCA`
- `sklearn.decomposition.LatentDirichletAllocation`
- Preprocessing
  - `sklearn.preprocessing.StandardScaler`
  - `sklearn.preprocessing.MinMaxScaler`
  - `sklearn.preprocessing.MaxAbsScaler`

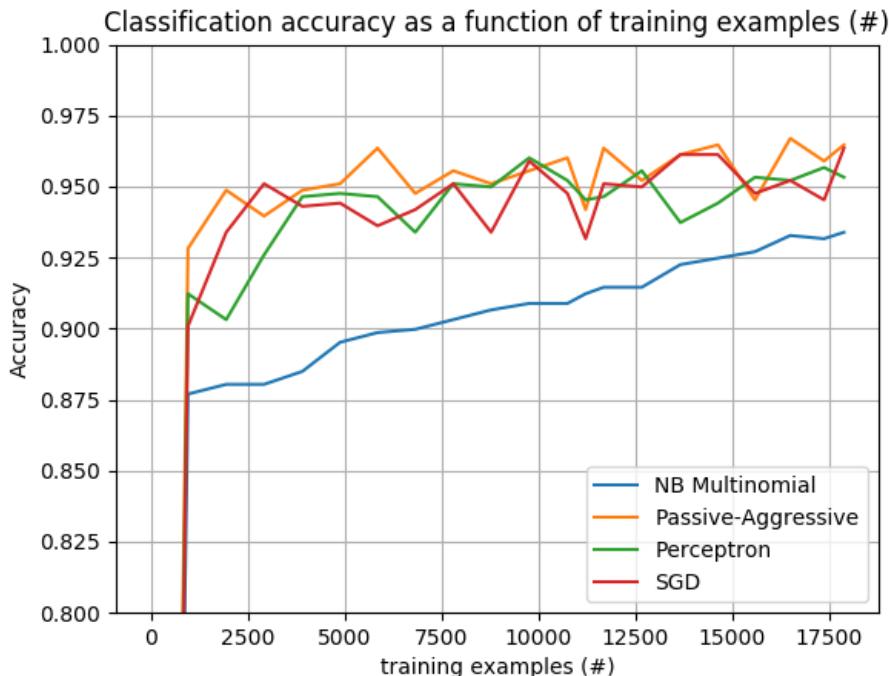

For classification, a somewhat important thing to note is that although a stateless feature extraction routine may be able to cope with new/unseen attributes, the incremental learner itself may be unable to cope with new/unseen targets classes. In this case you have to pass all the possible classes to the first `partial_fit` call using the `classes=` parameter.

Another aspect to consider when choosing a proper algorithm is that all of them don't put the same importance on each example over time. Namely, the Perceptron is still sensitive to badly labeled examples even after many examples whereas the SGD\* and PassiveAggressive\* families are more robust to this kind of artifacts. Conversely, the later also tend to give less importance to remarkably different, yet properly labeled examples when they come late in the stream as their learning rate decreases over time.

## Examples

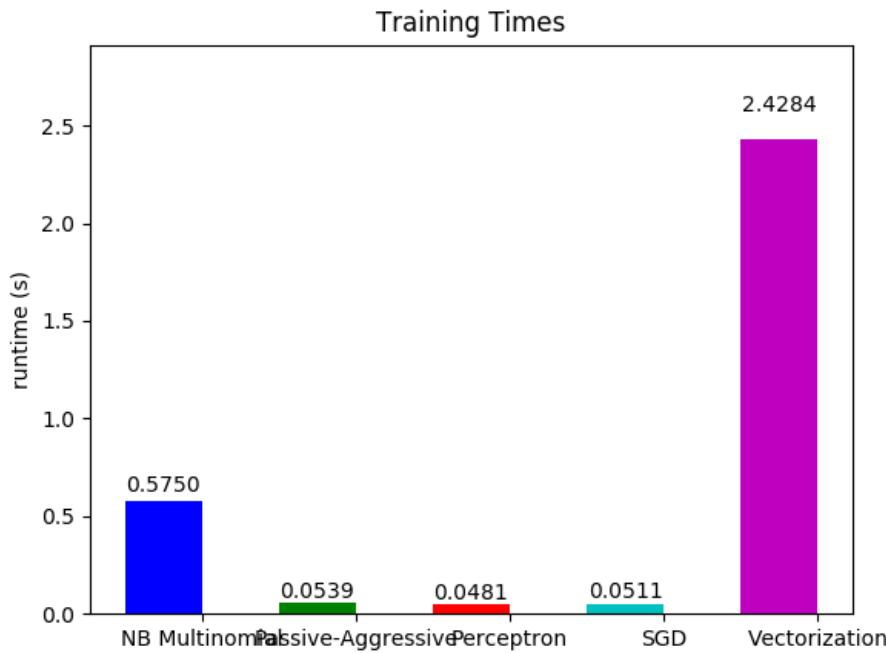

Finally, we have a full-fledged example of [Out-of-core classification of text documents](#). It is aimed at providing a starting point for people wanting to build out-of-core learning systems and demonstrates most of the notions discussed above.

Furthermore, it also shows the evolution of the performance of different algorithms with the number of processed examples.

Now looking at the computation time of the different parts, we see that the vectorization is much more expensive than learning itself. From the different algorithms, MultinomialNB is the most expensive, but its overhead can be

mitigated by increasing the size of the mini-batches (exercise: change `minibatch_size` to 100 and 10000 in the program and compare).

## Notes

## 3.7 Computational Performance

For some applications the performance (mainly latency and throughput at prediction time) of estimators is crucial. It may also be of interest to consider the training throughput but this is often less important in a production setup (where it often takes place offline).

We will review here the orders of magnitude you can expect from a number of scikit-learn estimators in different contexts and provide some tips and tricks for overcoming performance bottlenecks.

Prediction latency is measured as the elapsed time necessary to make a prediction (e.g. in micro-seconds). Latency is often viewed as a distribution and operations engineers often focus on the latency at a given percentile of this distribution (e.g. the 90 percentile).

Prediction throughput is defined as the number of predictions the software can deliver in a given amount of time (e.g. in predictions per second).

An important aspect of performance optimization is also that it can hurt prediction accuracy. Indeed, simpler models (e.g. linear instead of non-linear, or with fewer parameters) often run faster but are not always able to take into account the same exact properties of the data as more complex ones.

### 3.7.1 Prediction Latency

One of the most straight-forward concerns one may have when using/choosing a machine learning toolkit is the latency at which predictions can be made in a production environment.

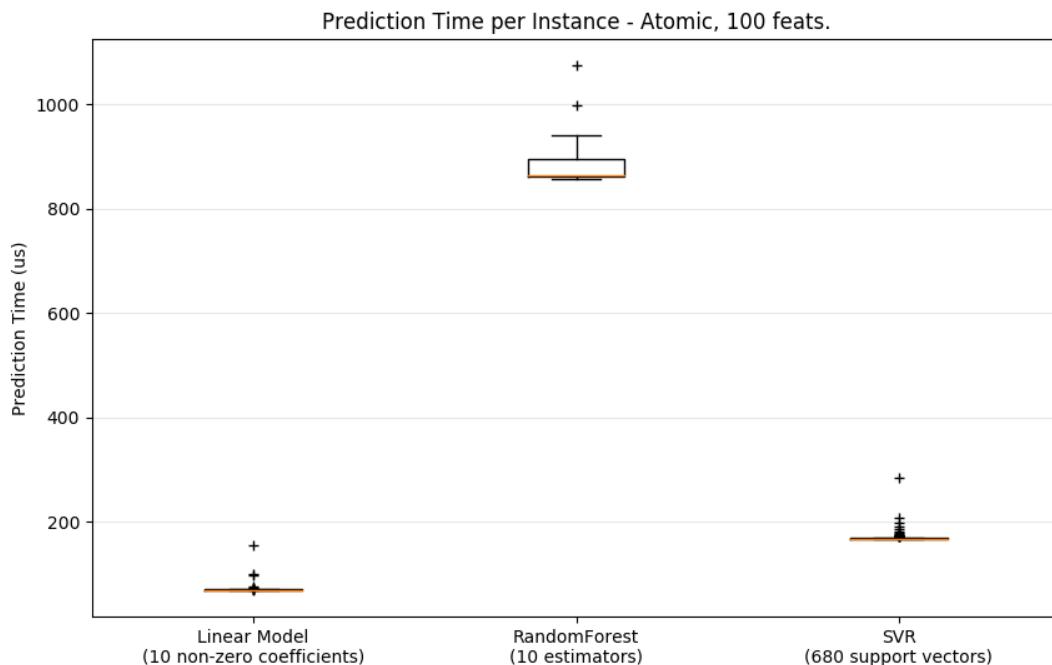

The main factors that influence the prediction latency are

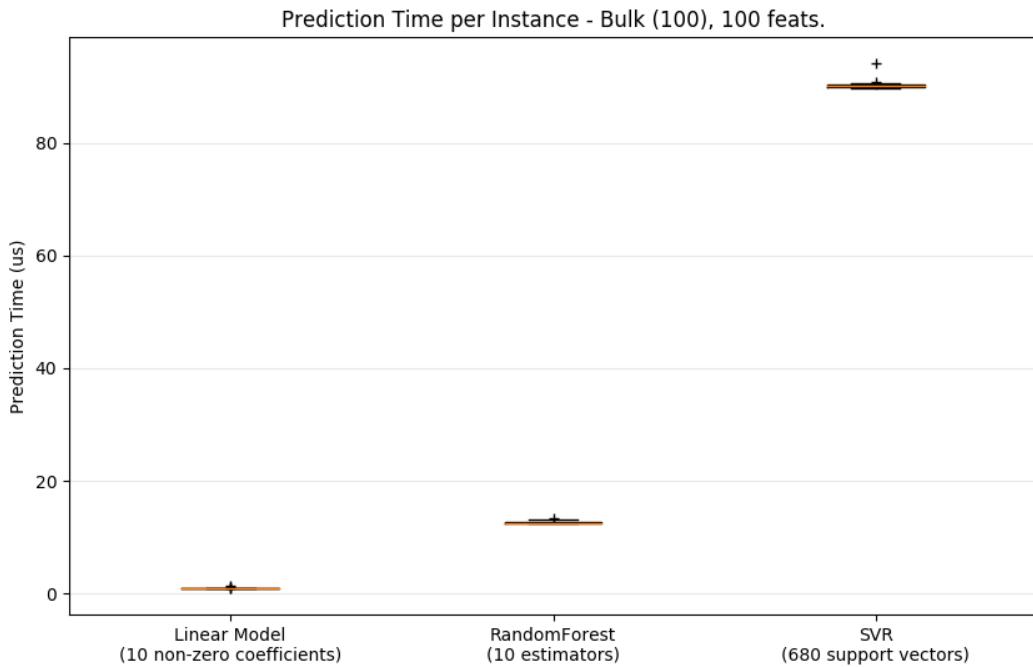

1. Number of features
2. Input data representation and sparsity
3. Model complexity
4. Feature extraction

A last major parameter is also the possibility to do predictions in bulk or one-at-a-time mode.

### Bulk versus Atomic mode

In general doing predictions in bulk (many instances at the same time) is more efficient for a number of reasons (branching predictability, CPU cache, linear algebra libraries optimizations etc.). Here we see on a setting with few features that independently of estimator choice the bulk mode is always faster, and for some of them by 1 to 2 orders of magnitude:

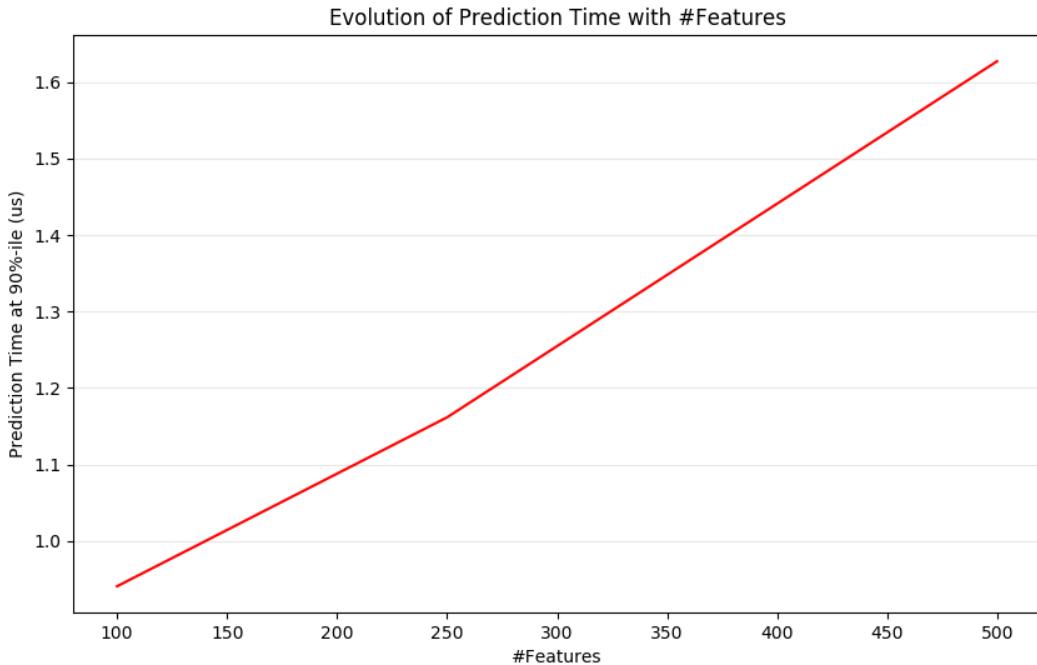

To benchmark different estimators for your case you can simply change the `n_features` parameter in this example: [Prediction Latency](#). This should give you an estimate of the order of magnitude of the prediction latency.

### Influence of the Number of Features

Obviously when the number of features increases so does the memory consumption of each example. Indeed, for a matrix of  $M$  instances with  $N$  features, the space complexity is in  $O(NM)$ . From a computing perspective it also means that the number of basic operations (e.g., multiplications for vector-matrix products in linear models) increases too. Here is a graph of the evolution of the prediction latency with the number of features:

Overall you can expect the prediction time to increase at least linearly with the number of features (non-linear cases can happen depending on the global memory footprint and estimator).

## Influence of the Input Data Representation

Scipy provides sparse matrix datastructures which are optimized for storing sparse data. The main feature of sparse formats is that you don't store zeros so if your data is sparse then you use much less memory. A non-zero value in a sparse ([CSR](#) or [CSC](#)) representation will only take on average one 32bit integer position + the 64 bit floating point value + an additional 32bit per row or column in the matrix. Using sparse input on a dense (or sparse) linear model can speedup prediction by quite a bit as only the non zero valued features impact the dot product and thus the model predictions. Hence if you have 100 non zeros in 1e6 dimensional space, you only need 100 multiply and add operation instead of 1e6.

Calculation over a dense representation, however, may leverage highly optimised vector operations and multithreading in BLAS, and tends to result in fewer CPU cache misses. So the sparsity should typically be quite high (10% non-zeros max, to be checked depending on the hardware) for the sparse input representation to be faster than the dense input representation on a machine with many CPUs and an optimized BLAS implementation.

Here is sample code to test the sparsity of your input:

```
def sparsity_ratio(X):
    return 1.0 - np.count_nonzero(X) / float(X.shape[0] * X.shape[1])
print("input sparsity ratio:", sparsity_ratio(X))
```

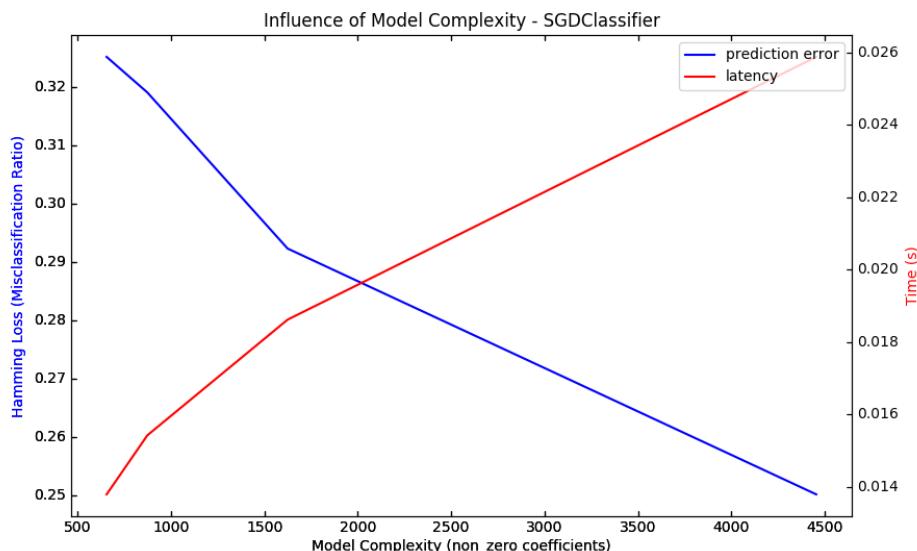

As a rule of thumb you can consider that if the sparsity ratio is greater than 90% you can probably benefit from sparse formats. Check Scipy's sparse matrix formats [documentation](#) for more information on how to build (or convert your data to) sparse matrix formats. Most of the time the [CSR](#) and [CSC](#) formats work best.

## Influence of the Model Complexity

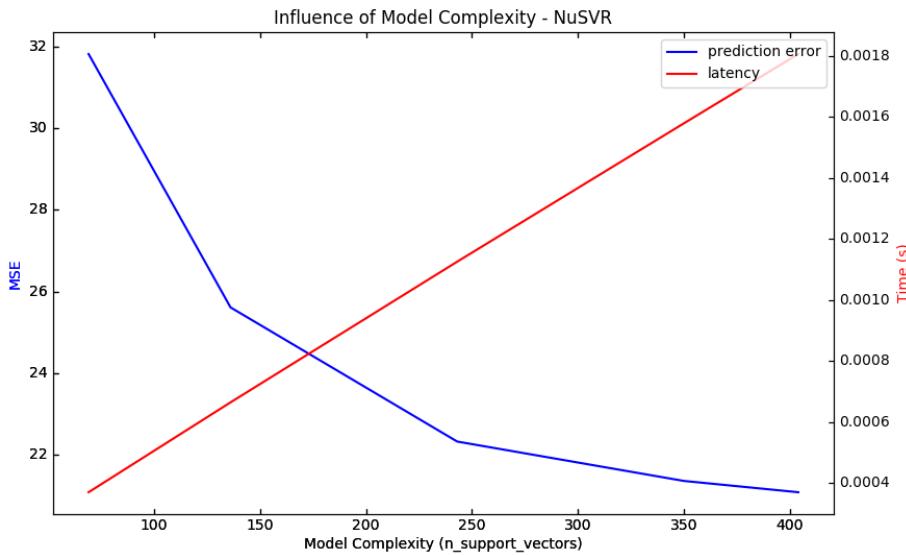

Generally speaking, when model complexity increases, predictive power and latency are supposed to increase. Increasing predictive power is usually interesting, but for many applications we would better not increase prediction latency too much. We will now review this idea for different families of supervised models.

For `sklearn.linear_model` (e.g. Lasso, ElasticNet, SGDClassifier/Regressor, Ridge & RidgeClassifier, PassiveAgressiveClassifier/Regressor, LinearSVC, LogisticRegression...) the decision function that is applied at prediction time is the same (a dot product), so latency should be equivalent.

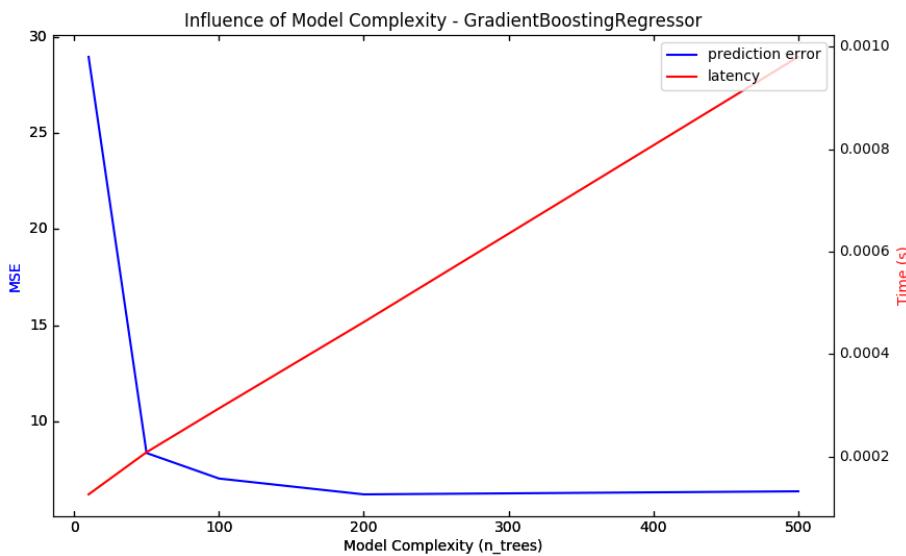

Here is an example using `sklearn.linear_model.stochastic_gradient.SGDClassifier` with the `elasticnet` penalty. The regularization strength is globally controlled by the `alpha` parameter. With a sufficiently high `alpha`, one can then increase the `l1_ratio` parameter of `elasticnet` to enforce various levels of sparsity in the model coefficients. Higher sparsity here is interpreted as less model complexity as we need fewer coefficients to describe it fully. Of course sparsity influences in turn the prediction time as the sparse dot-product takes time roughly proportional to the number of non-zero coefficients.

For the `sklearn.svm` family of algorithms with a non-linear kernel, the latency is tied to the number of support vectors (the fewer the faster). Latency and throughput should (asymptotically) grow linearly with the number of support vectors in a SVC or SVR model. The kernel will also influence the latency as it is used to compute the projection of the input vector once per support vector. In the following graph the `nu` parameter of `sklearn.svm.classes.NuSVR` was used to influence the number of support vectors.

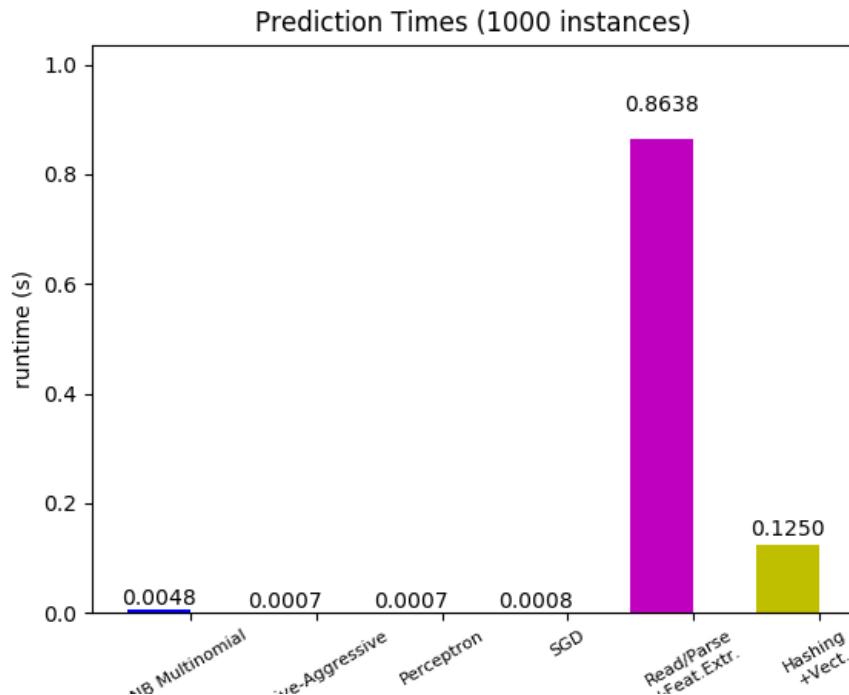

For `sklearn.ensemble` of trees (e.g. RandomForest, GBT, ExtraTrees etc) the number of trees and their depth play the most important role. Latency and throughput should scale linearly with the number of trees. In this case we used directly the `n_estimators` parameter of `sklearn.ensemble.GradientBoostingRegressor`.

In any case be warned that decreasing model complexity can hurt accuracy as mentioned above. For instance a non-linearly separable problem can be handled with a speedy linear model but prediction power will very likely suffer in the process.

## Feature Extraction Latency

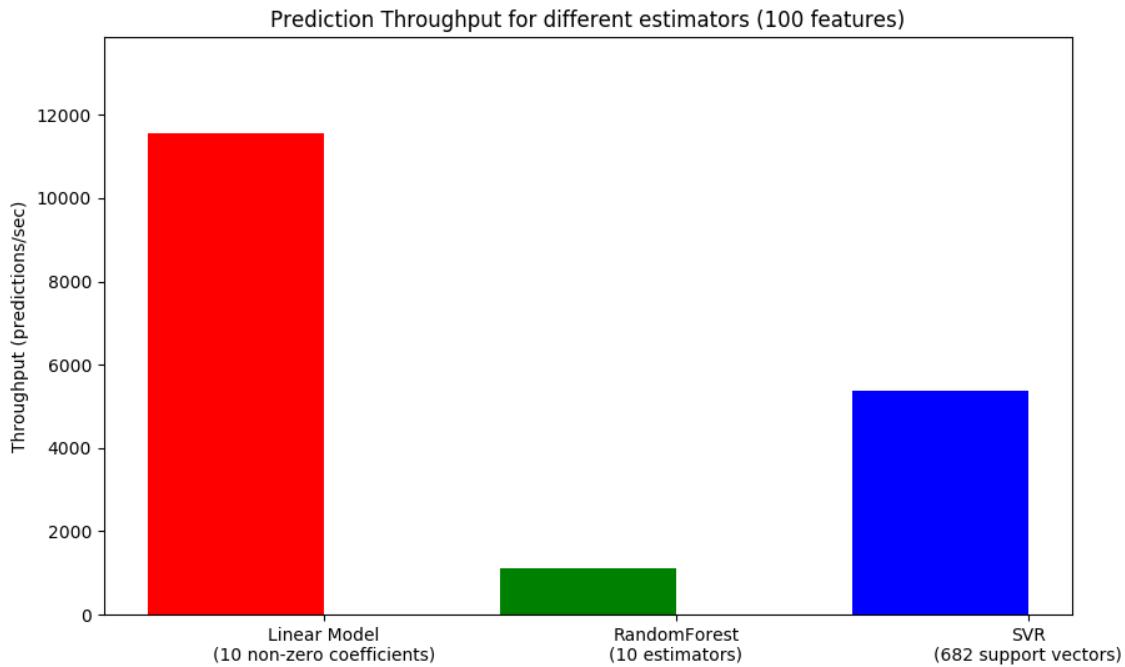

Most scikit-learn models are usually pretty fast as they are implemented either with compiled Cython extensions or optimized computing libraries. On the other hand, in many real world applications the feature extraction process (i.e. turning raw data like database rows or network packets into numpy arrays) governs the overall prediction time. For example on the Reuters text classification task the whole preparation (reading and parsing SGML files, tokenizing the text and hashing it into a common vector space) is taking 100 to 500 times more time than the actual prediction code, depending on the chosen model.

In many cases it is thus recommended to carefully time and profile your feature extraction code as it may be a good place to start optimizing when your overall latency is too slow for your application.

### 3.7.2 Prediction Throughput

Another important metric to care about when sizing production systems is the throughput i.e. the number of predictions you can make in a given amount of time. Here is a benchmark from the [Prediction Latency](#) example that measures this quantity for a number of estimators on synthetic data:

These throughputs are achieved on a single process. An obvious way to increase the throughput of your application is to spawn additional instances (usually processes in Python because of the [GIL](#)) that share the same model. One might also add machines to spread the load. A detailed explanation on how to achieve this is beyond the scope of this documentation though.

### 3.7.3 Tips and Tricks

#### Linear algebra libraries

As scikit-learn relies heavily on Numpy/Scipy and linear algebra in general it makes sense to take explicit care of the versions of these libraries. Basically, you ought to make sure that Numpy is built using an optimized [BLAS / LAPACK](#) library.

Not all models benefit from optimized BLAS and Lapack implementations. For instance models based on (randomized) decision trees typically do not rely on BLAS calls in their inner loops, nor do kernel SVMs (SVC, SVR, NuSVC, NuSVR). On the other hand a linear model implemented with a BLAS DGEMM call (via `numpy.dot`) will typically benefit hugely from a tuned BLAS implementation and lead to orders of magnitude speedup over a non-optimized BLAS.

You can display the BLAS / LAPACK implementation used by your NumPy / SciPy / scikit-learn install with the following commands:

```
from numpy.distutils.system_info import get_info
print(get_info('blas_opt'))
print(get_info('lapack_opt'))
```

#### Optimized BLAS / LAPACK implementations include:

- Atlas (need hardware specific tuning by rebuilding on the target machine)

- OpenBLAS
- MKL
- Apple Accelerate and vecLib frameworks (OSX only)

More information can be found on the [Scipy install](#) page and in this [blog post](#) from Daniel Nouri which has some nice step by step install instructions for Debian / Ubuntu.

**Warning:** Multithreaded BLAS libraries sometimes conflict with Python's `multiprocessing` module, which is used by e.g. `GridSearchCV` and most other estimators that take an `n_jobs` argument (with the exception of `SGDClassifier`, `SGDRegressor`, `Perceptron`, `PassiveAggressiveClassifier` and tree-based methods such as random forests). This is true of Apple's Accelerate and OpenBLAS when built with OpenMP support.

Besides scikit-learn, NumPy and SciPy also use BLAS internally, as explained earlier.

If you experience hanging subprocesses with `n_jobs>1` or `n_jobs=-1`, make sure you have a single-threaded BLAS library, or set `n_jobs=1`, or upgrade to Python 3.4 which has a new version of `multiprocessing` that should be immune to this problem.

## Model Compression

Model compression in scikit-learn only concerns linear models for the moment. In this context it means that we want to control the model sparsity (i.e. the number of non-zero coordinates in the model vectors). It is generally a good idea to combine model sparsity with sparse input data representation.

Here is sample code that illustrates the use of the `sparsify()` method:

```
clf = SGDRegressor(penalty='elasticnet', l1_ratio=0.25)
clf.fit(X_train, y_train).sparsify()
clf.predict(X_test)
```

In this example we prefer the `elasticnet` penalty as it is often a good compromise between model compactness and prediction power. One can also further tune the `l1_ratio` parameter (in combination with the regularization strength `alpha`) to control this tradeoff.

A typical [benchmark](#) on synthetic data yields a >30% decrease in latency when both the model and input are sparse (with 0.000024 and 0.027400 non-zero coefficients ratio respectively). Your mileage may vary depending on the sparsity and size of your data and model. Furthermore, sparsifying can be very useful to reduce the memory usage of predictive models deployed on production servers.

## Model Reshaping

Model reshaping consists in selecting only a portion of the available features to fit a model. In other words, if a model discards features during the learning phase we can then strip those from the input. This has several benefits. Firstly it reduces memory (and therefore time) overhead of the model itself. It also allows to discard explicit feature selection components in a pipeline once we know which features to keep from a previous run. Finally, it can help reduce processing time and I/O usage upstream in the data access and feature extraction layers by not collecting and building features that are discarded by the model. For instance if the raw data come from a database, it can make it possible to write simpler and faster queries or reduce I/O usage by making the queries return lighter records. At the moment, reshaping needs to be performed manually in scikit-learn. In the case of sparse input (particularly in CSR format), it is generally sufficient to not generate the relevant features, leaving their columns empty.

## GENERAL EXAMPLES

General-purpose and introductory examples for the scikit.

### 4.1 Plotting Cross-Validated Predictions

This example shows how to use `cross_val_predict` to visualize prediction errors.

```
from sklearn import datasets
from sklearn.model_selection import cross_val_predict
from sklearn import linear_model
import matplotlib.pyplot as plt
```

```
lr = linear_model.LinearRegression()
boston = datasets.load_boston()
y = boston.target

# cross_val_predict returns an array of the same size as `y` where each entry
# is a prediction obtained by cross validation:
predicted = cross_val_predict(lr, boston.data, y, cv=10)

fig, ax = plt.subplots()
ax.scatter(y, predicted)
ax.plot([y.min(), y.max()], [y.min(), y.max()], 'k--', lw=4)
ax.set_xlabel('Measured')
ax.set_ylabel('Predicted')
plt.show()
```

**Total running time of the script:** ( 0 minutes 0.120 seconds)

## 4.2 Isotonic Regression

An illustration of the isotonic regression on generated data. The isotonic regression finds a non-decreasing approximation of a function while minimizing the mean squared error on the training data. The benefit of such a model is that it does not assume any form for the target function such as linearity. For comparison a linear regression is also presented.

```
print(__doc__)

# Author: Nelle Varoquaux <nelle.varoquaux@gmail.com>
#         Alexandre Gramfort <alexandre.gramfort@inria.fr>
# License: BSD

import numpy as np
import matplotlib.pyplot as plt
from matplotlib.collections import LineCollection

from sklearn.linear_model import LinearRegression
from sklearn.isotonic import IsotonicRegression
from sklearn.utils import check_random_state

n = 100
x = np.arange(n)
rs = check_random_state(0)
y = rs.randint(-50, 50, size=(n,)) + 50. * np.log(1 + np.arange(n))
```

Fit IsotonicRegression and LinearRegression models

```
ir = IsotonicRegression()

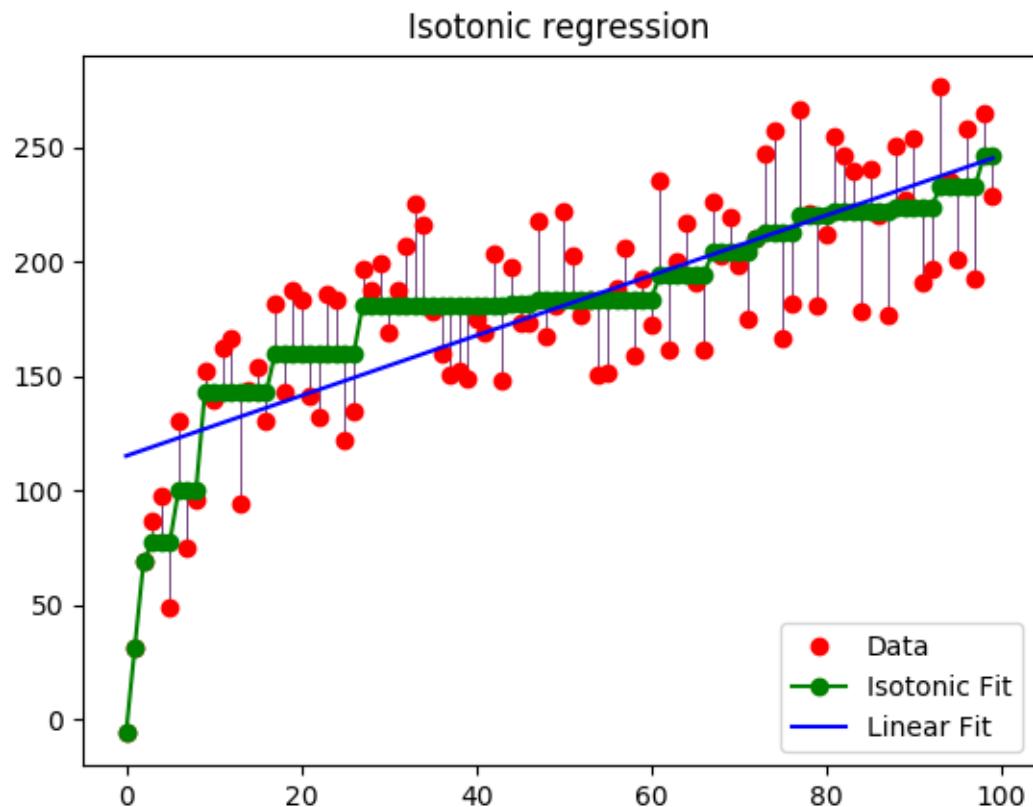

y_ = ir.fit_transform(x, y)
```

```
lr = LinearRegression()
lr.fit(x[:, np.newaxis], y) # x needs to be 2d for LinearRegression
```

plot result

```
segments = [[[i, y[i]], [i, y_[i]]] for i in range(n)]
lc = LineCollection(segments, zorder=0)
lc.set_array(np.ones(len(y)))
lc.set_linewidths(0.5 * np.ones(n))

fig = plt.figure()
plt.plot(x, y, 'r.', markersize=12)
plt.plot(x, y_, 'g.-', markersize=12)
plt.plot(x, lr.predict(x[:, np.newaxis]), 'b-')
plt.gca().add_collection(lc)
plt.legend(['Data', 'Isotonic Fit', 'Linear Fit'], loc='lower right')
plt.title('Isotonic regression')
plt.show()
```

**Total running time of the script:** ( 0 minutes 0.108 seconds)

## 4.3 Concatenating multiple feature extraction methods

In many real-world examples, there are many ways to extract features from a dataset. Often it is beneficial to combine several methods to obtain good performance. This example shows how to use `FeatureUnion` to combine features obtained by PCA and univariate selection.

Combining features using this transformer has the benefit that it allows cross validation and grid searches over the whole process.

The combination used in this example is not particularly helpful on this dataset and is only used to illustrate the usage of FeatureUnion.

## 4.5 Imputing missing values before building an estimator

This example shows that imputing the missing values can give better results than discarding the samples containing any missing value. Imputing does not always improve the predictions, so please check via cross-validation. Sometimes dropping rows or using marker values is more effective.

Missing values can be replaced by the mean, the median or the most frequent value using the `strategy` hyper-parameter. The median is a more robust estimator for data with high magnitude variables which could dominate results (otherwise known as a ‘long tail’).

Script output:

```

Score with the entire dataset = 0.56
Score without the samples containing missing values = 0.48
Score after imputation of the missing values = 0.55

```

In this case, imputing helps the classifier get close to the original score.

Out:

```

Score with the entire dataset = 0.56
Score without the samples containing missing values = 0.48
Score after imputation of the missing values = 0.57

```

```

## 4.6 Face completion with a multi-output estimators

This example shows the use of multi-output estimator to complete images. The goal is to predict the lower half of a face given its upper half.

The first column of images shows true faces. The next columns illustrate how extremely randomized trees, k nearest neighbors, linear regression and ridge regression complete the lower half of those faces.

Face completion with multi-output estimators

```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt

from sklearn.datasets import fetch_olivetti_faces
from sklearn.utils.validation import check_random_state

from sklearn.ensemble import ExtraTreesRegressor
from sklearn.neighbors import KNeighborsRegressor
from sklearn.linear_model import LinearRegression
from sklearn.linear_model import RidgeCV

# Load the faces datasets
data = fetch_olivetti_faces()
targets = data.target

data = data.images.reshape((len(data.images), -1))
train = data[targets < 30]
test = data[targets >= 30] # Test on independent people

# Test on a subset of people
n_faces = 5
rng = check_random_state(4)

## 4.7 Selecting dimensionality reduction with Pipeline and GridSearchCV

This example constructs a pipeline that does dimensionality reduction followed by prediction with a support vector classifier. It demonstrates the use of `GridSearchCV` and `Pipeline` to optimize over different classes of estimators in a single CV run – unsupervised PCA and NMF dimensionality reductions are compared to univariate feature selection during the grid search.

Additionally, `Pipeline` can be instantiated with the `memory` argument to memoize the transformers within the pipeline, avoiding to fit again the same transformers over and over.

Note that the use of `memory` to enable caching becomes interesting when the fitting of a transformer is costly.

### 4.7.1 Illustration of Pipeline and GridSearchCV

This section illustrates the use of a `Pipeline` with `GridSearchCV`

```
# Authors: Robert McGibbon, Joel Nothman, Guillaume Lemaitre

from __future__ import print_function, division

import numpy as np
import matplotlib.pyplot as plt
from sklearn.datasets import load_digits
from sklearn.model_selection import GridSearchCV
from sklearn.pipeline import Pipeline
from sklearn.svm import LinearSVC
from sklearn.decomposition import PCA, NMF
from sklearn.feature_selection import SelectKBest, chi2

print(__doc__)

pipe = Pipeline([
    ('reduce_dim', PCA()),
    ('classify', LinearSVC())
])

N_FEATURES_OPTIONS = [2, 4, 8]
C_OPTIONS = [1, 10, 100, 1000]
param_grid = [
    {
        'reduce_dim': [PCA(iterated_power=7), NMF()],
        'reduce_dim_n_components': N_FEATURES_OPTIONS,
        'classify_C': C_OPTIONS
    },
    {
        'reduce_dim': [SelectKBest(chi2)],
        'reduce_dim_k': N_FEATURES_OPTIONS,
        'classify_C': C_OPTIONS
    },
]
reducer_labels = ['PCA', 'NMF', 'KBest(chi2)']

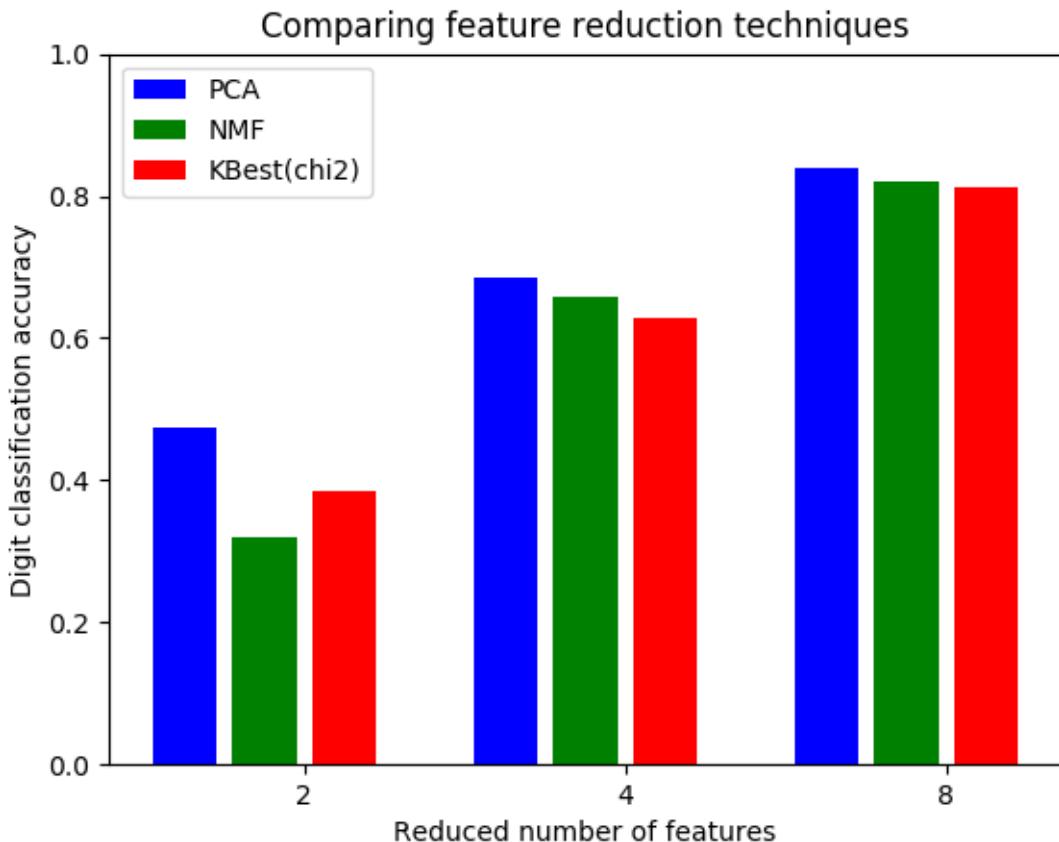

grid = GridSearchCV(pipe, cv=3, n_jobs=1, param_grid=param_grid)
digits = load_digits()
grid.fit(digits.data, digits.target)

mean_scores = np.array(grid.cv_results_['mean_test_score'])
# scores are in the order of param_grid iteration, which is alphabetical
mean_scores = mean_scores.reshape(len(C_OPTIONS), -1, len(N_FEATURES_OPTIONS))
# select score for best C
mean_scores = mean_scores.max(axis=0)
bar_offsets = (np.arange(len(N_FEATURES_OPTIONS)) *
               (len(reducer_labels) + 1) + .5)

plt.figure()
COLORS = 'bgrcmyk'
for i, (label, reducer_scores) in enumerate(zip(reducer_labels, mean_scores)):
    plt.bar(bar_offsets + i, reducer_scores, label=label, color=COLORS[i])

plt.title("Comparing feature reduction techniques")
plt.xlabel('Reduced number of features')
plt.xticks(bar_offsets + len(reducer_labels) / 2, N_FEATURES_OPTIONS)
plt.ylabel('Digit classification accuracy')
plt.ylim((0, 1))
```

```
plt.legend(loc='upper left')
```

#### 4.7.2 Caching transformers within a Pipeline

It is sometimes worthwhile storing the state of a specific transformer since it could be used again. Using a pipeline in `GridSearchCV` triggers such situations. Therefore, we use the argument `memory` to enable caching.

**Warning:** Note that this example is, however, only an illustration since for this specific case fitting PCA is not necessarily slower than loading the cache. Hence, use the `memory` constructor parameter when the fitting of a transformer is costly.

```
from tempfile import mkdtemp
from shutil import rmtree
from sklearn.externals.joblib import Memory

# Create a temporary folder to store the transformers of the pipeline
cachedir = mkdtemp()
memory = Memory(cachedir=cachedir, verbose=10)
cached_pipe = Pipeline([('reduce_dim', PCA()),
                      ('classify', LinearSVC())],
                      memory=memory)
```

```
# This time, a cached pipeline will be used within the grid search
grid = GridSearchCV(cached_pipe, cv=3, n_jobs=1, param_grid=param_grid)
digits = load_digits()
grid.fit(digits.data, digits.target)

# Delete the temporary cache before exiting
rmtree(cachedir)
```

```

The PCA fitting is only computed at the evaluation of the first configuration of the C parameter of the LinearSVC classifier. The other configurations of C will trigger the loading of the cached PCA estimator data, leading to save processing time. Therefore, the use of caching the pipeline using memory is highly beneficial when fitting a transformer is costly.

```
plt.show()
```

**Total running time of the script:** ( 1 minutes 23.667 seconds)

## 4.8 Multilabel classification

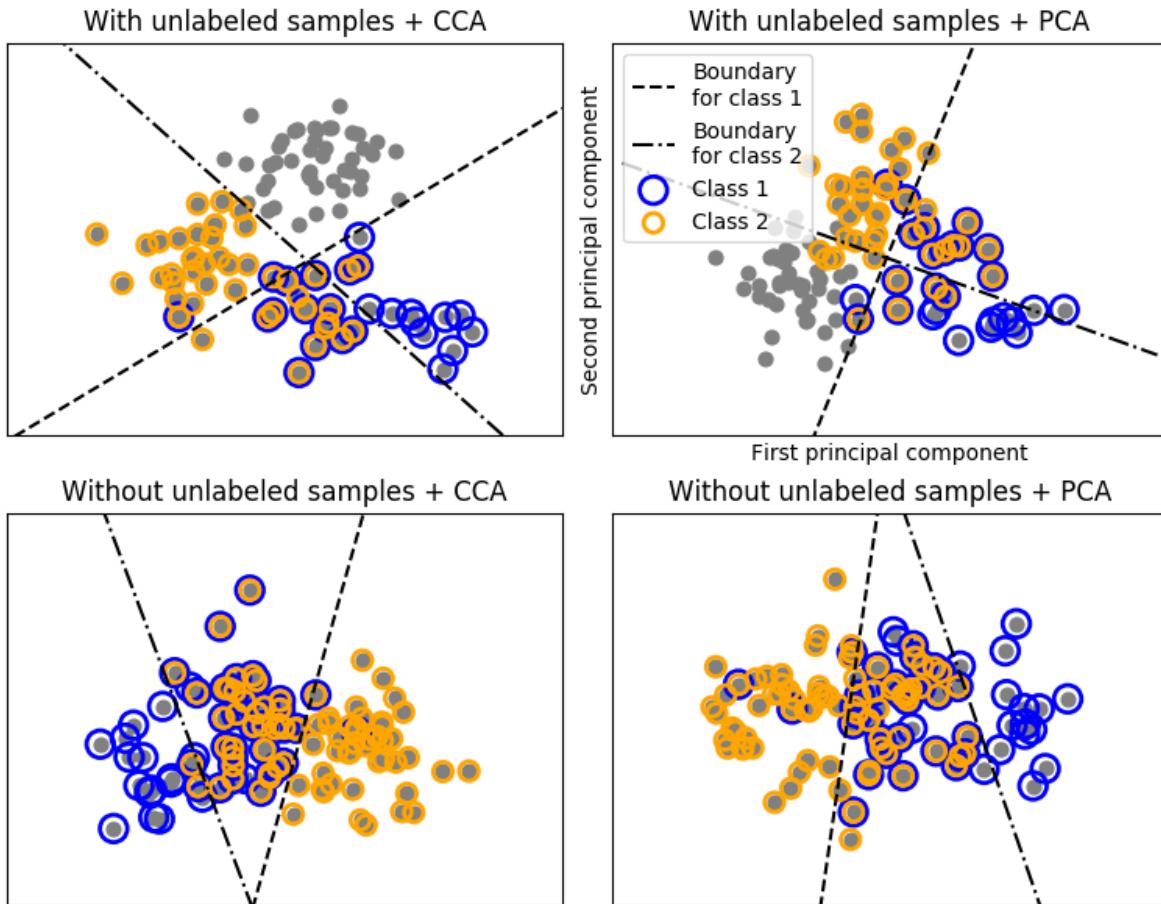

This example simulates a multi-label document classification problem. The dataset is generated randomly based on the following process:

- pick the number of labels:  $n \sim \text{Poisson}(n\_labels)$
- $n$  times, choose a class  $c: c \sim \text{Multinomial}(\theta)$
- pick the document length:  $k \sim \text{Poisson}(\text{length})$
- $k$  times, choose a word:  $w \sim \text{Multinomial}(\theta_c)$

In the above process, rejection sampling is used to make sure that  $n$  is more than 2, and that the document length is never zero. Likewise, we reject classes which have already been chosen. The documents that are assigned to both classes are plotted surrounded by two colored circles.

The classification is performed by projecting to the first two principal components found by PCA and CCA for visualisation purposes, followed by using the `sklearn.multiclass.OneVsRestClassifier` metaclassifier using two SVCs with linear kernels to learn a discriminative model for each class. Note that PCA is used to perform an unsupervised dimensionality reduction, while CCA is used to perform a supervised one.

Note: in the plot, “unlabeled samples” does not mean that we don’t know the labels (as in semi-supervised learning) but that the samples simply do *not* have a label.

## 4.9 The Johnson-Lindenstrauss bound for embedding with random projections

The Johnson-Lindenstrauss lemma states that any high dimensional dataset can be randomly projected into a lower dimensional Euclidean space while controlling the distortion in the pairwise distances.

### 4.9.1 Theoretical bounds

The distortion introduced by a random projection  $p$  is asserted by the fact that  $p$  is defining an  $\epsilon$ -embedding with good probability as defined by:

$$(1 - \epsilon)\|u - v\|^2 < \|p(u) - p(v)\|^2 < (1 + \epsilon)\|u - v\|^2$$

Where  $u$  and  $v$  are any rows taken from a dataset of shape  $[n\_samples, n\_features]$  and  $p$  is a projection by a random Gaussian  $N(0, 1)$  matrix with shape  $[n\_components, n\_features]$  (or a sparse Achlioptas matrix).

The minimum number of components to guarantees the  $\epsilon$ -embedding is given by:

$$n\_components \geq 4\log(n\_samples)/(\epsilon^2/2 - \epsilon\sqrt{\epsilon}/3)$$

The first plot shows that with an increasing number of samples  $n\_samples$ , the minimal number of dimensions  $n\_components$  increased logarithmically in order to guarantee an  $\epsilon$ -embedding.

The second plot shows that an increase of the admissible distortion  $\epsilon$  allows to reduce drastically the minimal number of dimensions  $n\_components$  for a given number of samples  $n\_samples$ .

### 4.9.2 Empirical validation

We validate the above bounds on the digits dataset or on the 20 newsgroups text document (TF-IDF word frequencies) dataset:

- for the digits dataset, some 8x8 gray level pixels data for 500 handwritten digits pictures are randomly projected to spaces for various larger number of dimensions  $n\_components$ .
- for the 20 newsgroups dataset some 500 documents with 100k features in total are projected using a sparse random matrix to smaller euclidean spaces with various values for the target number of dimensions  $n\_components$ .

The default dataset is the digits dataset. To run the example on the twenty newsgroups dataset, pass the `--twenty-newsgroups` command line argument to this script.

For each value of  $n\_components$ , we plot:

- 2D distribution of sample pairs with pairwise distances in original and projected spaces as x and y axis respectively.
- 1D histogram of the ratio of those distances (projected / original).

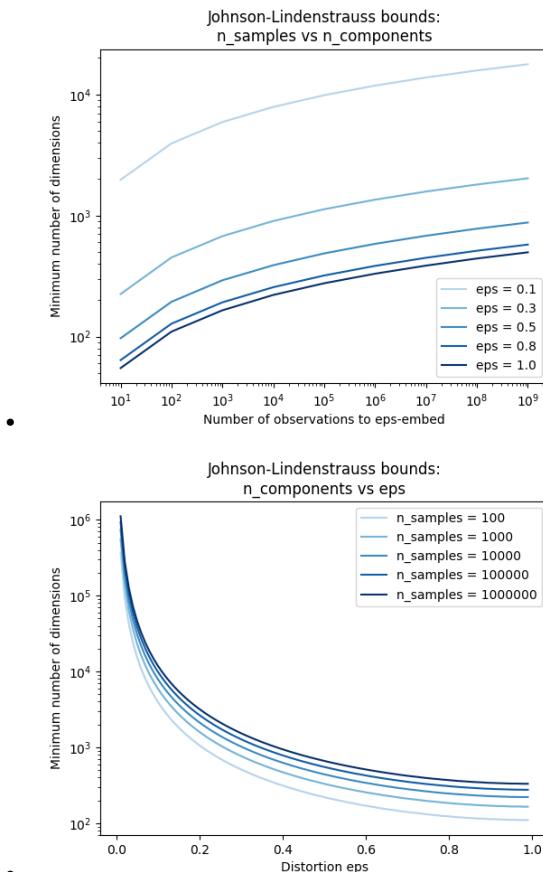

We can see that for low values of `n_components` the distribution is wide with many distorted pairs and a skewed distribution (due to the hard limit of zero ratio on the left as distances are always positives) while for larger values of `n_components` the distortion is controlled and the distances are well preserved by the random projection.

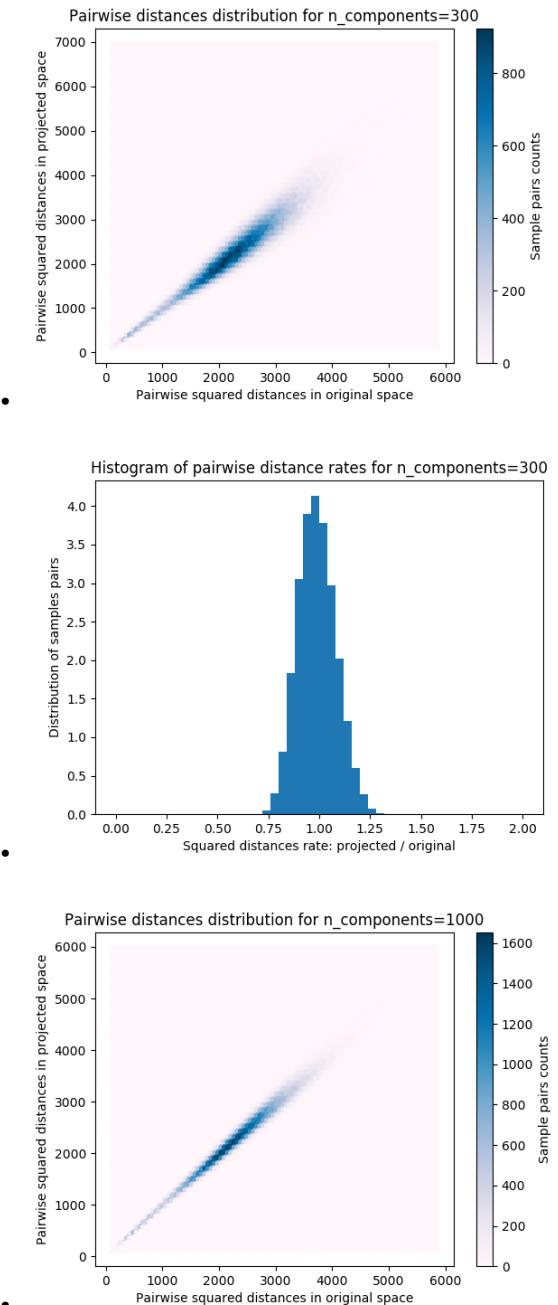

### 4.9.3 Remarks

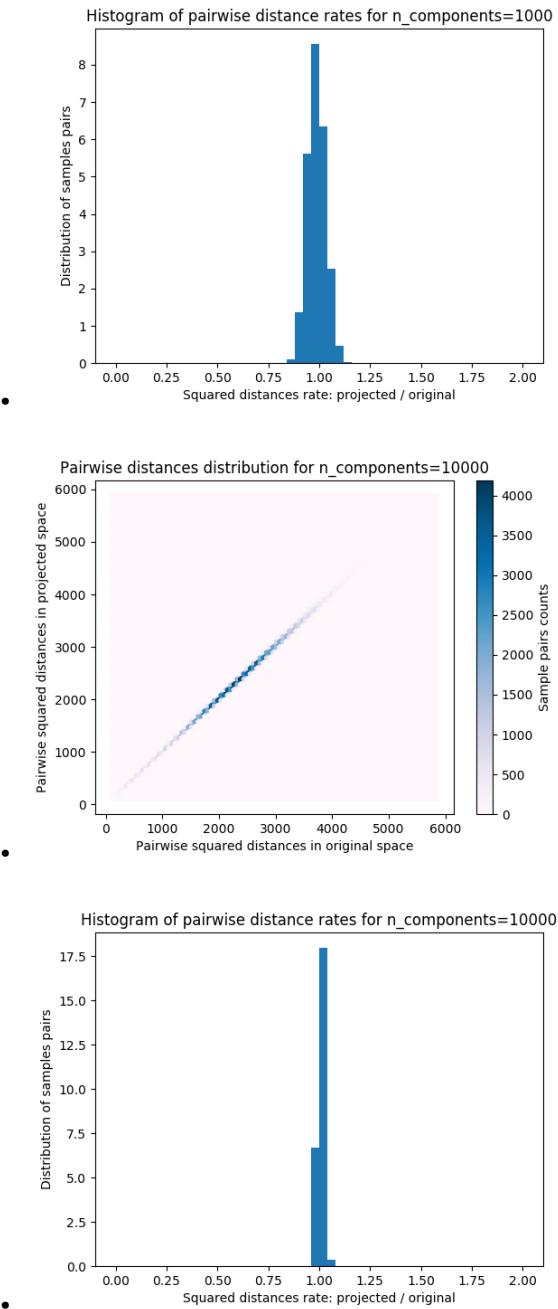

According to the JL lemma, projecting 500 samples without too much distortion will require at least several thousands dimensions, irrespective of the number of features of the original dataset.

Hence using random projections on the digits dataset which only has 64 features in the input space does not make sense: it does not allow for dimensionality reduction in this case.

On the twenty newsgroups on the other hand the dimensionality can be decreased from 56436 down to 10000 while reasonably preserving pairwise distances.

Out:

```

Embedding 500 samples with dim 64 using various random projections
Projected 500 samples from 64 to 300 in 0.024s
Random matrix with size: 0.029MB
Mean distances rate: 0.99 (0.09)
Projected 500 samples from 64 to 1000 in 0.046s
Random matrix with size: 0.096MB
Mean distances rate: 0.99 (0.04)
Projected 500 samples from 64 to 10000 in 0.448s
Random matrix with size: 0.961MB
Mean distances rate: 1.01 (0.01)

```

## 4.10 Comparison of kernel ridge regression and SVR

Both kernel ridge regression (KRR) and SVR learn a non-linear function by employing the kernel trick, i.e., they learn a linear function in the space induced by the respective kernel which corresponds to a non-linear function in the original space. They differ in the loss functions (ridge versus epsilon-insensitive loss). In contrast to SVR, fitting a KRR can be done in closed-form and is typically faster for medium-sized datasets. On the other hand, the learned model is non-sparse and thus slower than SVR at prediction-time.

This example illustrates both methods on an artificial dataset, which consists of a sinusoidal target function and strong noise added to every fifth datapoint. The first figure compares the learned model of KRR and SVR when both complexity/regularization and bandwidth of the RBF kernel are optimized using grid-search. The learned functions are very similar; however, fitting KRR is approx. seven times faster than fitting SVR (both with grid-search). However, prediction of 100000 target values is more than three times faster with SVR since it has learned a sparse model using only approx. 1/3 of the 100 training datapoints as support vectors.

The next figure compares the time for fitting and prediction of KRR and SVR for different sizes of the training set. Fitting KRR is faster than SVR for medium-sized training sets (less than 1000 samples); however, for larger training sets SVR scales better. With regard to prediction time, SVR is faster than KRR for all sizes of the training set because of the learned sparse solution. Note that the degree of sparsity and thus the prediction time depends on the parameters epsilon and C of the SVR.

## 4.11 Feature Union with Heterogeneous Data Sources

Datasets can often contain components of that require different feature extraction and processing pipelines. This scenario might occur when:

1. Your dataset consists of heterogeneous data types (e.g. raster images and text captions)
2. Your dataset is stored in a Pandas DataFrame and different columns require different processing pipelines.

This example demonstrates how to use `sklearn.feature_extraction.FeatureUnion` on a dataset containing different types of features. We use the 20-newsgroups dataset and compute standard bag-of-words features for the subject line and body in separate pipelines as well as ad hoc features on the body. We combine them (with weights) using a FeatureUnion and finally train a classifier on the combined set of features.

The choice of features is not particularly helpful, but serves to illustrate the technique.

```

from sklearn.svm import SVC

class ItemSelector(BaseEstimator, TransformerMixin):
    """For data grouped by feature, select subset of data at a provided key.

    The data is expected to be stored in a 2D data structure, where the first
    index is over features and the second is over samples. i.e.

    >> len(data[key]) == n_samples

    Please note that this is the opposite convention to scikit-learn feature
    matrixes (where the first index corresponds to sample).

    ItemSelector only requires that the collection implement getitem
    (data[key]). Examples include: a dict of lists, 2D numpy array, Pandas
    DataFrame, numpy record array, etc.

    >> data = {'a': [1, 5, 2, 5, 2, 8],
               'b': [9, 4, 1, 4, 1, 3]}
    >> ds = ItemSelector(key='a')
    >> data['a'] == ds.transform(data)

    ItemSelector is not designed to handle data grouped by sample. (e.g. a
    list of dicts). If your data is structured this way, consider a
    transformer along the lines of `sklearn.feature_extraction.DictVectorizer`.

## 4.12 Explicit feature map approximation for RBF kernels

An example illustrating the approximation of the feature map of an RBF kernel.

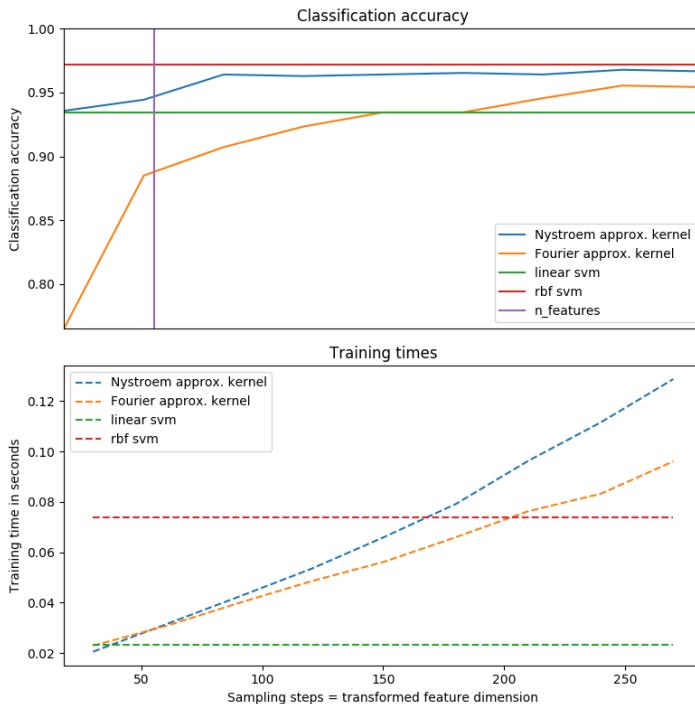

It shows how to use `RBFSampler` and `Nystroem` to approximate the feature map of an RBF kernel for classification with an SVM on the digits dataset. Results using a linear SVM in the original space, a linear SVM using the approximate mappings and using a kernelized SVM are compared. Timings and accuracy for varying amounts of Monte Carlo samplings (in the case of `RBFSampler`, which uses random Fourier features) and different sized subsets of the training set (for `Nystroem`) for the approximate mapping are shown.

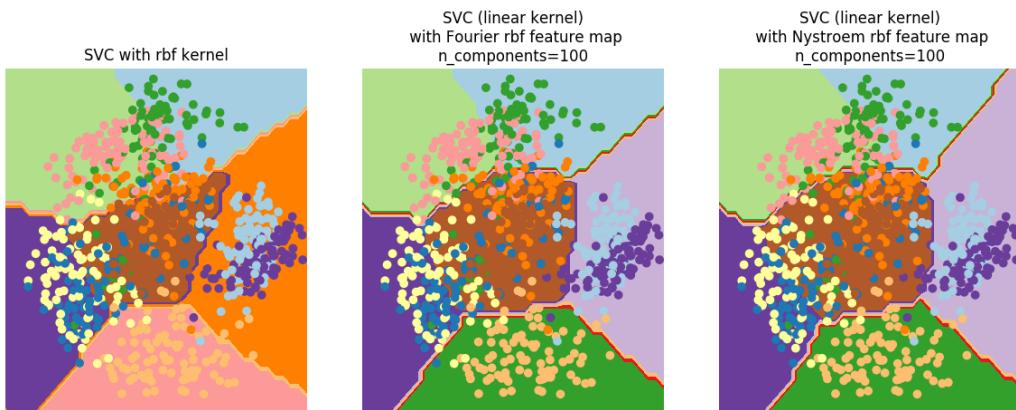

Please note that the dataset here is not large enough to show the benefits of kernel approximation, as the exact SVM is still reasonably fast.

Sampling more dimensions clearly leads to better classification results, but comes at a greater cost. This means there is a tradeoff between runtime and accuracy, given by the parameter `n_components`. Note that solving the Linear SVM and also the approximate kernel SVM could be greatly accelerated by using stochastic gradient descent via `sklearn.linear_model.SGDClassifier`. This is not easily possible for the case of the kernelized SVM.

The second plot visualized the decision surfaces of the RBF kernel SVM and the linear SVM with approximate kernel maps. The plot shows decision surfaces of the classifiers projected onto the first two principal components of the data. This visualization should be taken with a grain of salt since it is just an interesting slice through the decision surface in 64 dimensions. In particular note that a datapoint (represented as a dot) does not necessarily be classified into the region it is lying in, since it will not lie on the plane that the first two principal components span.

The usage of `RBFSampler` and `Nystroem` is described in detail in [Kernel Approximation](#).

## EXAMPLES BASED ON REAL WORLD DATASETS

Applications to real world problems with some medium sized datasets or interactive user interface.

### 5.1 Outlier detection on a real data set

This example illustrates the need for robust covariance estimation on a real data set. It is useful both for outlier detection and for a better understanding of the data structure.

We selected two sets of two variables from the Boston housing data set as an illustration of what kind of analysis can be done with several outlier detection tools. For the purpose of visualization, we are working with two-dimensional examples, but one should be aware that things are not so trivial in high-dimension, as it will be pointed out.

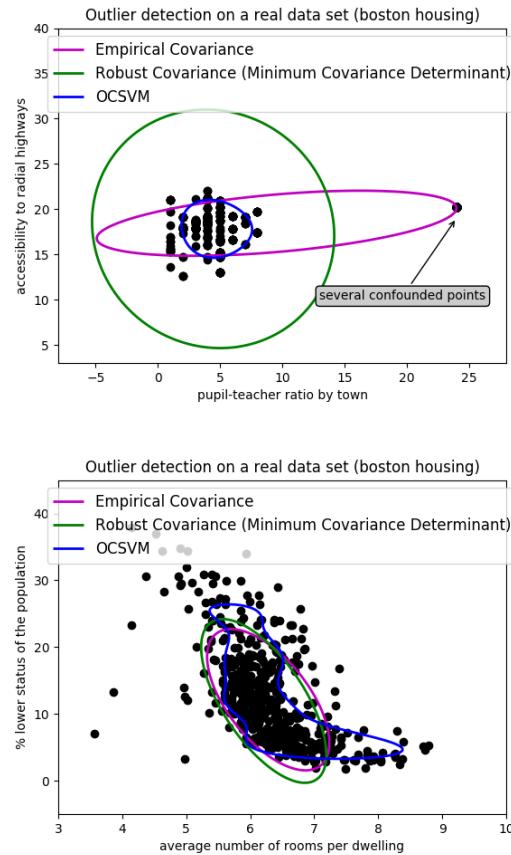

In both examples below, the main result is that the empirical covariance estimate, as a non-robust one, is highly influenced by the heterogeneous structure of the observations. Although the robust covariance estimate is able to focus on the main mode of the data distribution, it sticks to the assumption that the data should be Gaussian distributed, yielding some biased estimation of the data structure, but yet accurate to some extent. The One-Class SVM does not assume any parametric form of the data distribution and can therefore model the complex shape of the data much better.

#### 5.1.1 First example

The first example illustrates how robust covariance estimation can help concentrating on a relevant cluster when another one exists. Here, many observations are confounded into one and break down the empirical covariance estimation. Of course, some screening tools would have pointed out the presence of two clusters (Support Vector Machines, Gaussian Mixture Models, univariate outlier detection, ...). But had it been a high-dimensional example, none of these could be applied that easily.

#### 5.1.2 Second example

The second example shows the ability of the Minimum Covariance Determinant robust estimator of covariance to concentrate on the main mode of the data distribution: the location seems to be well estimated, although the covariance is hard to estimate due to the banana-shaped distribution. Anyway, we can get rid of some outlying observations. The One-Class SVM is able to capture the real data structure, but the difficulty is to adjust its kernel bandwidth parameter so as to obtain a good compromise between the shape of the data scatter matrix and the risk of over-fitting the data.

## 5.2 Compressive sensing: tomography reconstruction with L1 prior (Lasso)

This example shows the reconstruction of an image from a set of parallel projections, acquired along different angles. Such a dataset is acquired in **computed tomography** (CT).

Without any prior information on the sample, the number of projections required to reconstruct the image is of the order of the linear size  $l$  of the image (in pixels). For simplicity we consider here a sparse image, where only pixels on the boundary of objects have a non-zero value. Such data could correspond for example to a cellular material. Note however that most images are sparse in a different basis, such as the Haar wavelets. Only  $1/7$  projections are acquired, therefore it is necessary to use prior information available on the sample (its sparsity): this is an example of **compressive sensing**.

The tomography projection operation is a linear transformation. In addition to the data-fidelity term corresponding to a linear regression, we penalize the L1 norm of the image to account for its sparsity. The resulting optimization problem is called the **Lasso**. We use the class `sklearn.linear_model.Lasso`, that uses the coordinate descent algorithm. Importantly, this implementation is more computationally efficient on a sparse matrix, than the projection operator used here.

The reconstruction with L1 penalization gives a result with zero error (all pixels are successfully labeled with 0 or 1), even if noise was added to the projections. In comparison, an L2 penalization (`sklearn.linear_model.Ridge`) produces a large number of labeling errors for the pixels. Important artifacts are observed on the reconstructed image, contrary to the L1 penalization. Note in particular the circular artifact separating the pixels in the corners, that have contributed to fewer projections than the central disk.

## 5.4 Topic extraction with Non-negative Matrix Factorizationand Latent Dirichlet Allocation

This is an example of applying `sklearn.decomposition.NMF` and `sklearn.decomposition.LatentDirichletAllocation` on a corpus of documents and extract additive models of the topic structure of the corpus. The output is a list of topics, each represented as a list of terms (weights are not shown).

Non-negative Matrix Factorization is applied with two different objective functions: the Frobenius norm, and the generalized Kullback-Leibler divergence. The latter is equivalent to Probabilistic Latent Semantic Indexing.

The default parameters (`n_samples / n_features / n_components`) should make the example runnable in a couple of tens of seconds. You can try to increase the dimensions of the problem, but be aware that the time complexity is polynomial in NMF. In LDA, the time complexity is proportional to (`n_samples * iterations`).

## 5.5 Model Complexity Influence

Demonstrate how model complexity influences both prediction accuracy and computational performance.

The dataset is the Boston Housing dataset (resp. 20 Newsgroups) for regression (resp. classification).

For each class of models we make the model complexity vary through the choice of relevant model parameters and measure the influence on both computational performance (latency) and predictive power (MSE or Hamming Loss).

## 5.6 Species distribution modeling

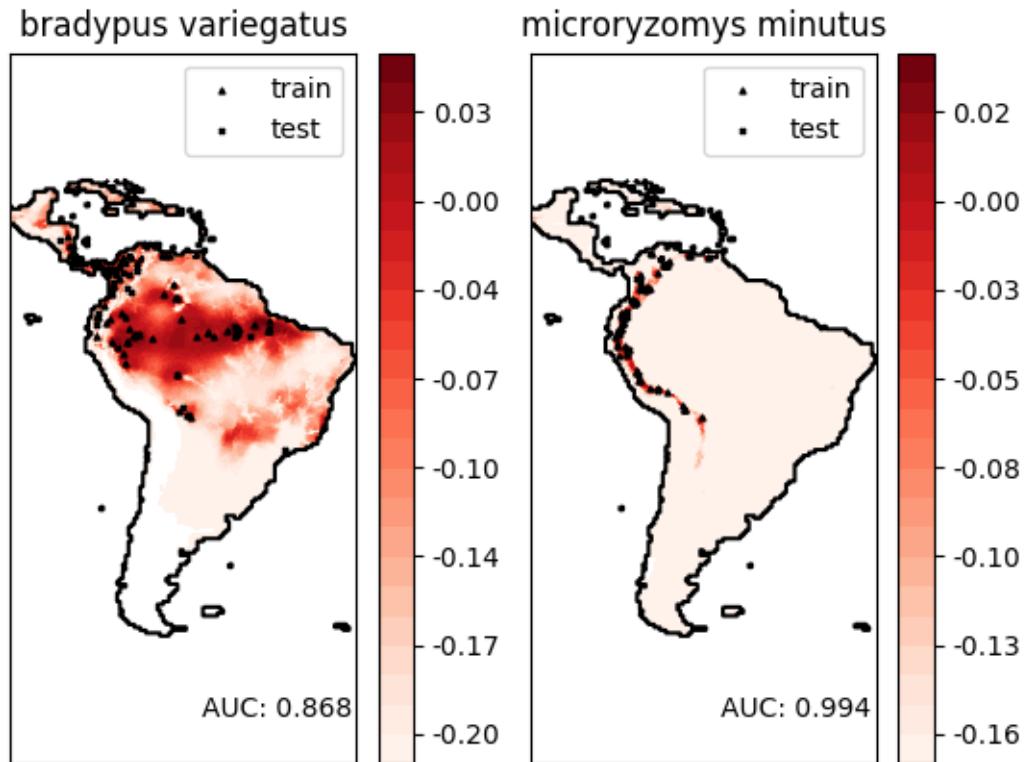

Modeling species' geographic distributions is an important problem in conservation biology. In this example we model the geographic distribution of two south american mammals given past observations and 14 environmental variables. Since we have only positive examples (there are no unsuccessful observations), we cast this problem as a density estimation problem and use the *OneClassSVM* provided by the package `sklearn.svm` as our modeling tool. The dataset is provided by Phillips et. al. (2006). If available, the example uses `basemap` to plot the coast lines and national boundaries of South America.

The two species are:

- “`Bradypus variegatus`”, the Brown-throated Sloth.
- “`Microryzomys minutus`”, also known as the Forest Small Rice Rat, a rodent that lives in Peru, Colombia, Ecuador, Peru, and Venezuela.

### 5.6.1 References

## 5.7 Visualizing the stock market structure

This example employs several unsupervised learning techniques to extract the stock market structure from variations in historical quotes.

The quantity that we use is the daily variation in quote price: quotes that are linked tend to cofluctuate during a day.

### 5.7.1 Learning a graph structure

We use sparse inverse covariance estimation to find which quotes are correlated conditionally on the others. Specifically, sparse inverse covariance gives us a graph, that is a list of connection. For each symbol, the symbols that it is connected too are those useful to explain its fluctuations.

### 5.7.2 Clustering

We use clustering to group together quotes that behave similarly. Here, amongst the *various clustering techniques* available in the scikit-learn, we use *Affinity Propagation* as it does not enforce equal-size clusters, and it can choose automatically the number of clusters from the data.

Note that this gives us a different indication than the graph, as the graph reflects conditional relations between variables, while the clustering reflects marginal properties: variables clustered together can be considered as having a similar impact at the level of the full stock market.

### 5.7.3 Embedding in 2D space

For visualization purposes, we need to lay out the different symbols on a 2D canvas. For this we use *Manifold learning* techniques to retrieve 2D embedding.

## 5.7.4 Visualization

The output of the 3 models are combined in a 2D graph where nodes represents the stocks and edges the:

- cluster labels are used to define the color of the nodes
- the sparse covariance model is used to display the strength of the edges
- the 2D embedding is used to position the nodes in the plan

This example has a fair amount of visualization-related code, as visualization is crucial here to display the graph. One of the challenge is to position the labels minimizing overlap. For this we use an heuristic based on the direction of the nearest neighbor along each axis.

## 5.8 Wikipedia principal eigenvector

A classical way to assert the relative importance of vertices in a graph is to compute the principal eigenvector of the adjacency matrix so as to assign to each vertex the values of the components of the first eigenvector as a centrality score:

[https://en.wikipedia.org/wiki/Eigenvector\\_centrality](https://en.wikipedia.org/wiki/Eigenvector_centrality)

On the graph of webpages and links those values are called the PageRank scores by Google.

The goal of this example is to analyze the graph of links inside wikipedia articles to rank articles by relative importance according to this eigenvector centrality.

The traditional way to compute the principal eigenvector is to use the power iteration method:

[https://en.wikipedia.org/wiki/Power\\_iteration](https://en.wikipedia.org/wiki/Power_iteration)

Here the computation is achieved thanks to Martinsson's Randomized SVD algorithm implemented in the scikit.

The graph data is fetched from the DBpedia dumps. DBpedia is an extraction of the latent structured data of the Wikipedia content.

## 5.9 Libsvm GUI

A simple graphical frontend for Libsvm mainly intended for didactic purposes. You can create data points by point and click and visualize the decision region induced by different kernels and parameter settings.

To create positive examples click the left mouse button; to create negative examples click the right button.

If all examples are from the same class, it uses a one-class SVM.

## 5.10 Prediction Latency

This is an example showing the prediction latency of various scikit-learn estimators.

The goal is to measure the latency one can expect when doing predictions either in bulk or atomic (i.e. one by one) mode.

The plots represent the distribution of the prediction latency as a boxplot.

## 5.11 Out-of-core classification of text documents

This is an example showing how scikit-learn can be used for classification using an out-of-core approach: learning from data that doesn't fit into main memory. We make use of an online classifier, i.e., one that supports the `partial_fit` method, that will be fed with batches of examples. To guarantee that the features space remains the same over time we leverage a HashingVectorizer that will project each example into the same feature space. This is especially useful in the case of text classification where new features (words) may appear in each batch.

The dataset used in this example is Reuters-21578 as provided by the UCI ML repository. It will be automatically downloaded and uncompressed on first run.

The plot represents the learning curve of the classifier: the evolution of classification accuracy over the course of the mini-batches. Accuracy is measured on the first 1000 samples, held out as a validation set.

To limit the memory consumption, we queue examples up to a fixed amount before feeding them to the learner.

## BICLUSTERING

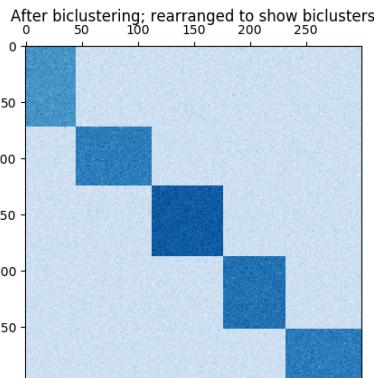

Examples concerning the `sklearn.cluster.bicluster` module.

### 6.1 A demo of the Spectral Co-Clustering algorithm

This example demonstrates how to generate a dataset and bicluster it using the Spectral Co-Clustering algorithm.

The dataset is generated using the `make_biclusters` function, which creates a matrix of small values and implants bicluster with large values. The rows and columns are then shuffled and passed to the Spectral Co-Clustering algorithm. Rearranging the shuffled matrix to make biclusters contiguous shows how accurately the algorithm found the biclusters.

## 6.2 A demo of the Spectral Biclustering algorithm

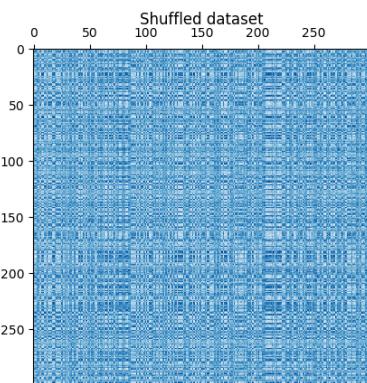

This example demonstrates how to generate a checkerboard dataset and bicluster it using the Spectral Biclustering algorithm.

The data is generated with the `make_checkerboard` function, then shuffled and passed to the Spectral Biclustering algorithm. The rows and columns of the shuffled matrix are rearranged to show the biclusters found by the algorithm.

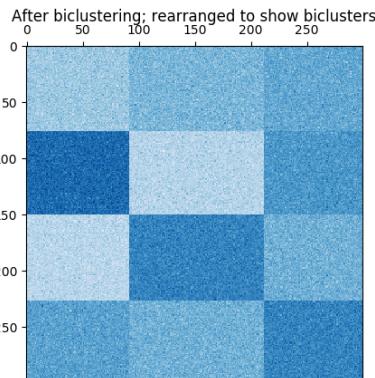

The outer product of the row and column label vectors shows a representation of the checkerboard structure.

## 6.3 Biclustering documents with the Spectral Co-clustering algorithm

This example demonstrates the Spectral Co-clustering algorithm on the twenty newsgroups dataset. The ‘comp.os.ms-windows.misc’ category is excluded because it contains many posts containing nothing but data.

The TF-IDF vectorized posts form a word frequency matrix, which is then biclustered using Dhillon’s Spectral Co-Clustering algorithm. The resulting document-word biclusters indicate subsets words used more often in those subsets documents.

For a few of the best biclusters, its most common document categories and its ten most important words get printed. The best biclusters are determined by their normalized cut. The best words are determined by comparing their sums inside and outside the bicluster.

For comparison, the documents are also clustered using MiniBatchKMeans. The document clusters derived from the biclusters achieve a better V-measure than clusters found by MiniBatchKMeans.

Out:

```

Vectorizing...
Coclustering...

```

```

Done in 6.07s. V-measure: 0.4445
MiniBatchKMeans...
Done in 13.90s. V-measure: 0.3309

## CALIBRATION

Examples illustrating the calibration of predicted probabilities of classifiers.

### 7.1 Comparison of Calibration of Classifiers

Well calibrated classifiers are probabilistic classifiers for which the output of the predict\_proba method can be directly interpreted as a confidence level. For instance a well calibrated (binary) classifier should classify the samples such that among the samples to which it gave a predict\_proba value close to 0.8, approx. 80% actually belong to the positive class.

LogisticRegression returns well calibrated predictions as it directly optimizes log-loss. In contrast, the other methods return biased probabilities, with different biases per method:

- GaussianNaiveBayes tends to push probabilities to 0 or 1 (note the counts in the histograms). This is mainly because it makes the assumption that features are conditionally independent given the class, which is not the case in this dataset which contains 2 redundant features.
- RandomForestClassifier shows the opposite behavior: the histograms show peaks at approx. 0.2 and 0.9 probability, while probabilities close to 0 or 1 are very rare. An explanation for this is given by Niculescu-Mizil and Caruana [1]: “Methods such as bagging and random forests that average predictions from a base set of models can have difficulty making predictions near 0 and 1 because variance in the underlying base models will bias predictions that should be near zero or one away from these values. Because predictions are restricted to the interval [0,1], errors caused by variance tend to be one- sided near zero and one. For example, if a model should predict  $p = 0$  for a case, the only way bagging can achieve this is if all bagged trees predict zero. If we add noise to the trees that bagging is averaging over, this noise will cause some trees to predict values larger than 0 for this case, thus moving the average prediction of the bagged ensemble away from 0. We observe this effect most strongly with random forests because the base-level trees trained with random forests have relatively high variance due to feature subsetting.” As a result, the calibration curve shows a characteristic sigmoid shape, indicating that the classifier could trust its “intuition” more and return probabilities closer to 0 or 1 typically.
- Support Vector Classification (SVC) shows an even more sigmoid curve as the RandomForestClassifier, which is typical for maximum-margin methods (compare Niculescu-Mizil and Caruana [1]), which focus on hard samples that are close to the decision boundary (the support vectors).

## 7.2 Probability Calibration curves

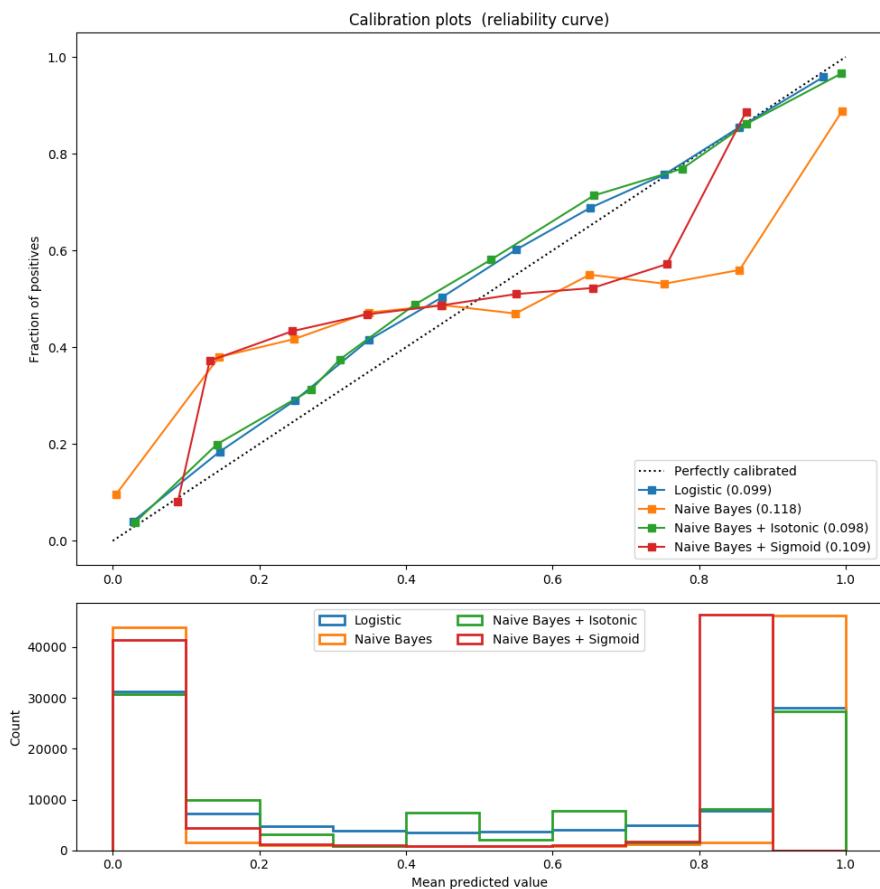

When performing classification one often wants to predict not only the class label, but also the associated probability. This probability gives some kind of confidence on the prediction. This example demonstrates how to display how well calibrated the predicted probabilities are and how to calibrate an uncalibrated classifier.

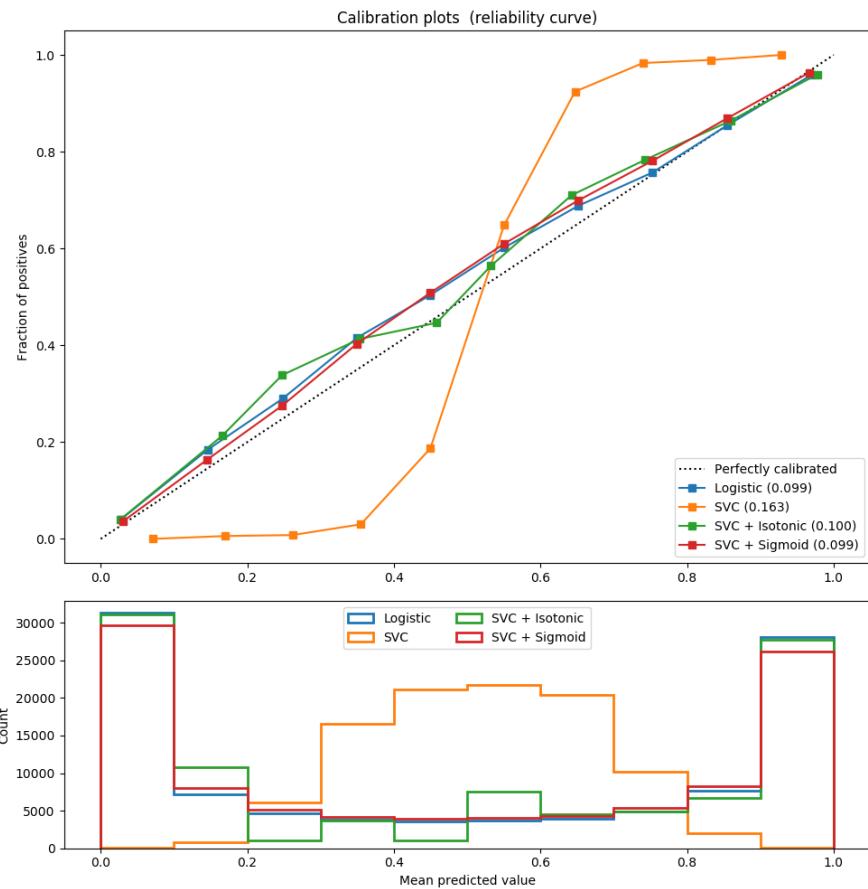

The experiment is performed on an artificial dataset for binary classification with 100.000 samples (1.000 of them are used for model fitting) with 20 features. Of the 20 features, only 2 are informative and 10 are redundant. The first figure shows the estimated probabilities obtained with logistic regression, Gaussian naive Bayes, and Gaussian naive Bayes with both isotonic calibration and sigmoid calibration. The calibration performance is evaluated with Brier score, reported in the legend (the smaller the better). One can observe here that logistic regression is well calibrated while raw Gaussian naive Bayes performs very badly. This is because of the redundant features which violate the assumption of feature-independence and result in an overly confident classifier, which is indicated by the typical transposed-sigmoid curve.

Calibration of the probabilities of Gaussian naive Bayes with isotonic regression can fix this issue as can be seen from the nearly diagonal calibration curve. Sigmoid calibration also improves the brier score slightly, albeit not as strongly as the non-parametric isotonic regression. This can be attributed to the fact that we have plenty of calibration data such that the greater flexibility of the non-parametric model can be exploited.

The second figure shows the calibration curve of a linear support-vector classifier (LinearSVC). LinearSVC shows the opposite behavior as Gaussian naive Bayes: the calibration curve has a sigmoid curve, which is typical for an under-confident classifier. In the case of LinearSVC, this is caused by the margin property of the hinge loss, which lets the model focus on hard samples that are close to the decision boundary (the support vectors).

Both kinds of calibration can fix this issue and yield nearly identical results. This shows that sigmoid calibration can deal with situations where the calibration curve of the base classifier is sigmoid (e.g., for LinearSVC) but not where it is transposed-sigmoid (e.g., Gaussian naive Bayes).

## 7.3 Probability calibration of classifiers

When performing classification you often want to predict not only the class label, but also the associated probability. This probability gives you some kind of confidence on the prediction. However, not all classifiers provide well-calibrated probabilities, some being over-confident while others being under-confident. Thus, a separate calibration of predicted probabilities is often desirable as a postprocessing. This example illustrates two different methods for this calibration and evaluates the quality of the returned probabilities using Brier's score (see [https://en.wikipedia.org/wiki/Brier\\_score](https://en.wikipedia.org/wiki/Brier_score)).

Compared are the estimated probability using a Gaussian naive Bayes classifier without calibration, with a sigmoid calibration, and with a non-parametric isotonic calibration. One can observe that only the non-parametric model is able to provide a probability calibration that returns probabilities close to the expected 0.5 for most of the samples belonging to the middle cluster with heterogeneous labels. This results in a significantly improved Brier score.

## 7.4 Probability Calibration for 3-class classification

This example illustrates how sigmoid calibration changes predicted probabilities for a 3-class classification problem. Illustrated is the standard 2-simplex, where the three corners correspond to the three classes. Arrows point from the

probability vectors predicted by an uncalibrated classifier to the probability vectors predicted by the same classifier after sigmoid calibration on a hold-out validation set. Colors indicate the true class of an instance (red: class 1, green: class 2, blue: class 3).

The base classifier is a random forest classifier with 25 base estimators (trees). If this classifier is trained on all 800 training datapoints, it is overly confident in its predictions and thus incurs a large log-loss. Calibrating an identical classifier, which was trained on 600 datapoints, with method='sigmoid' on the remaining 200 datapoints reduces the confidence of the predictions, i.e., moves the probability vectors from the edges of the simplex towards the center. This calibration results in a lower log-loss. Note that an alternative would have been to increase the number of base estimators which would have resulted in a similar decrease in log-loss.

Out:

```
Log-loss of
* uncalibrated classifier trained on 800 datapoints: 1.280
* classifier trained on 600 datapoints and calibrated on 200 datapoint: 0.534
```

## 8.3 Plot classification probability

Plot the classification probability for different classifiers. We use a 3 class dataset, and we classify it with a Support Vector classifier, L1 and L2 penalized logistic regression with either a One-Vs-Rest or multinomial setting, and Gaussian process classification.

The logistic regression is not a multiclass classifier out of the box. As a result it can identify only the first class.

Probability

Out:

```
classif_rate for L1 logistic : 79.333333
classif_rate for L2 logistic (OvR) : 76.666667
classif_rate for Linear SVC : 82.000000
classif_rate for L2 logistic (Multinomial) : 82.000000
classif_rate for GPC : 82.666667
```

## 8.4 Classifier comparison

A comparison of a several classifiers in scikit-learn on synthetic datasets. The point of this example is to illustrate the nature of decision boundaries of different classifiers. This should be taken with a grain of salt, as the intuition conveyed by these examples does not necessarily carry over to real datasets.

Particularly in high-dimensional spaces, data can more easily be separated linearly and the simplicity of classifiers such as naive Bayes and linear SVMs might lead to better generalization than is achieved by other classifiers.

The plots show training points in solid colors and testing points semi-transparent. The lower right shows the classification accuracy on the test set.

## 8.5 Linear and Quadratic Discriminant Analysis with covariance ellipsoid

This example plots the covariance ellipsoids of each class and decision boundary learned by LDA and QDA. The ellipsoids display the double standard deviation for each class. With LDA, the standard deviation is the same for all the classes, while each class has its own standard deviation with QDA.

```

print(__doc__)

from scipy import linalg
import numpy as np
import matplotlib.pyplot as plt
import matplotlib as mpl
from matplotlib import colors

## 9.4 Demonstration of k-means assumptions

This example is meant to illustrate situations where k-means will produce unintuitive and possibly unexpected clusters. In the first three plots, the input data does not conform to some implicit assumption that k-means makes and undesirable clusters are produced as a result. In the last plot, k-means returns intuitive clusters despite unevenly sized blobs.

```

## 9.5 Online learning of a dictionary of parts of faces

This example uses a large dataset of faces to learn a set of 20 x 20 images patches that constitute faces.

From the programming standpoint, it is interesting because it shows how to use the online API of the scikit-learn to process a very large dataset by chunks. The way we proceed is that we load an image at a time and extract randomly 50 patches from this image. Once we have accumulated 500 of these patches (using 10 images), we run the *partial\_fit* method of the online KMeans object, MiniBatchKMeans.

The verbose setting on the MiniBatchKMeans enables us to see that some clusters are reassigned during the successive calls to partial-fit. This is because the number of patches that they represent has become too low, and it is better to

choose a random new cluster.

```
print(__doc__)

import time

import matplotlib.pyplot as plt
import numpy as np

from sklearn import datasets
from sklearn.cluster import MiniBatchKMeans
from sklearn.feature_extraction.image import extract_patches_2d

faces = datasets.fetch_olivetti_faces()
```

Learn the dictionary of images

```
print('Learning the dictionary... ')
rng = np.random.RandomState(0)

## 9.7 Segmenting the picture of a raccoon face in regions

This example uses *Spectral clustering* on a graph created from voxel-to-voxel difference on an image to break this image into multiple partly-homogeneous regions.

This procedure (spectral clustering on an image) is an efficient approximate solution for finding normalized graph cuts.

There are two options to assign labels:

- with ‘kmeans’ spectral clustering will cluster samples in the embedding space using a kmeans algorithm
- whereas ‘discrete’ will iteratively search for the closest partition space to the embedding space.

```

## 9.8 Hierarchical clustering: structured vs unstructured ward

Example builds a swiss roll dataset and runs hierarchical clustering on their position.

For more information, see [Hierarchical clustering](#).

In a first step, the hierarchical clustering is performed without connectivity constraints on the structure and is solely based on distance, whereas in a second step the clustering is restricted to the k-Nearest Neighbors graph: it's a hierarchical clustering with structure prior.

Some of the clusters learned without connectivity constraints do not respect the structure of the swiss roll and extend across different folds of the manifolds. On the opposite, when opposing connectivity constraints, the clusters form a nice parcellation of the swiss roll.

## 9.10 Agglomerative clustering with and without structure

This example shows the effect of imposing a connectivity graph to capture local structure in the data. The graph is simply the graph of 20 nearest neighbors.

Two consequences of imposing a connectivity can be seen. First clustering with a connectivity matrix is much faster.

Second, when using a connectivity matrix, average and complete linkage are unstable and tend to create a few clusters that grow very quickly. Indeed, average and complete linkage fight this percolation behavior by considering all the

distances between two clusters when merging them. The connectivity graph breaks this mechanism. This effect is more pronounced for very sparse graphs (try decreasing the number of neighbors in kneighbors\_graph) and with complete linkage. In particular, having a very small number of neighbors in the graph, imposes a geometry that is close to that of single linkage, which is well known to have this percolation instability.

```

## 9.12 K-means Clustering

The plots display firstly what a K-means algorithm would yield using three clusters. It is then shown what the effect of a bad initialization is on the classification process: By setting n\_init to only 1 (default is 10), the amount of times that the algorithm will be run with different centroid seeds is reduced. The next plot displays what using eight clusters would deliver and finally the ground truth.

## 9.13 Spectral clustering for image segmentation

In this example, an image with connected circles is generated and spectral clustering is used to separate the circles.

In these settings, the *Spectral clustering* approach solves the problem known as ‘normalized graph cuts’: the image is seen as a graph of connected voxels, and the spectral clustering algorithm amounts to choosing graph cuts defining regions while minimizing the ratio of the gradient along the cut, and the volume of the region.

As the algorithm tries to balance the volume (ie balance the region sizes), if we take circles with different sizes, the segmentation fails.

In addition, as there is no useful information in the intensity of the image, or its gradient, we choose to perform the spectral clustering on a graph that is only weakly informed by the gradient. This is close to performing a Voronoi partition of the graph.

In addition, we use the mask of the objects to restrict the graph to the outline of the objects. In this example, we are interested in separating the objects one from the other, and not from the background.

```

## 9.14 Various Agglomerative Clustering on a 2D embedding of digits

An illustration of various linkage option for agglomerative clustering on a 2D embedding of the digits dataset.

The goal of this example is to show intuitively how the metrics behave, and not to find good clusters for the digits. This is why the example works on a 2D embedding.

What this example shows us is the behavior “rich getting richer” of agglomerative clustering that tends to create uneven cluster sizes. This behavior is especially pronounced for the average linkage strategy, that ends up with a couple of singleton clusters.

Out:

```
Computing embedding
Done.
ward : 0.40s

## 9.15 Color Quantization using K-Means

Performs a pixel-wise Vector Quantization (VQ) of an image of the summer palace (China), reducing the number of colors required to show the image from 96,615 unique colors to 64, while preserving the overall appearance quality.

In this example, pixels are represented in a 3D-space and K-means is used to find 64 color clusters. In the image processing literature, the codebook obtained from K-means (the cluster centers) is called the color palette. Using a single byte, up to 256 colors can be addressed, whereas an RGB encoding requires 3 bytes per pixel. The GIF file format, for example, uses such a palette.

For comparison, a quantized image using a random codebook (colors picked up randomly) is also shown.

Out:

```
Fitting model on a small sub-sample of the data
done in 0.475s.
Predicting color indices on the full image (k-means)
done in 0.228s.
Predicting color indices on the full image (random)
done in 0.231s.
```

```

## 9.16 Agglomerative clustering with different metrics

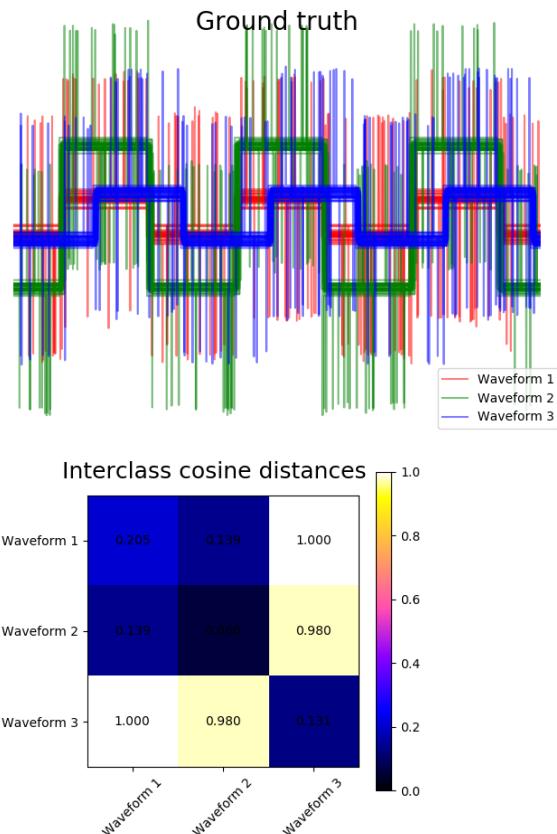

Demonstrates the effect of different metrics on the hierarchical clustering.

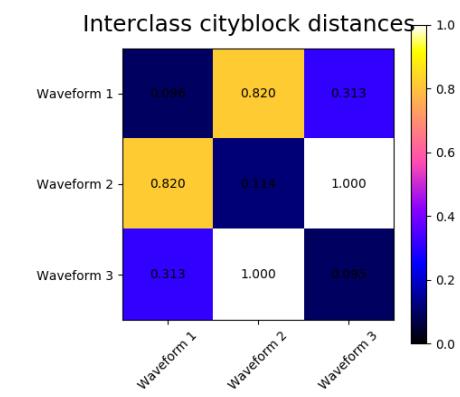

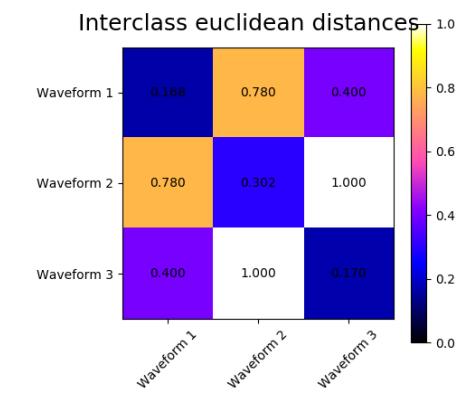

The example is engineered to show the effect of the choice of different metrics. It is applied to waveforms, which can be seen as high-dimensional vector. Indeed, the difference between metrics is usually more pronounced in high dimension (in particular for euclidean and cityblock).

We generate data from three groups of waveforms. Two of the waveforms (waveform 1 and waveform 2) are proportional one to the other. The cosine distance is invariant to a scaling of the data, as a result, it cannot distinguish these two waveforms. Thus even with no noise, clustering using this distance will not separate out waveform 1 and 2.

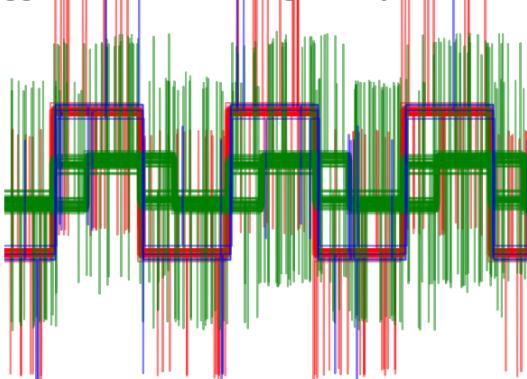

We add observation noise to these waveforms. We generate very sparse noise: only 6% of the time points contain noise. As a result, the  $\ell_1$  norm of this noise (ie “cityblock” distance) is much smaller than its  $\ell_2$  norm (“euclidean” distance). This can be seen on the inter-class distance matrices: the values on the diagonal, that characterize the spread of the class, are much bigger for the Euclidean distance than for the cityblock distance.

When we apply clustering to the data, we find that the clustering reflects what was in the distance matrices. Indeed, for the Euclidean distance, the classes are ill-separated because of the noise, and thus the clustering does not separate the waveforms. For the cityblock distance, the separation is good and the waveform classes are recovered. Finally, the cosine distance does not separate at all waveform 1 and 2, thus the clustering puts them in the same cluster.

## 9.17 Comparison of the K-Means and MiniBatchKMeans clustering algorithms

We want to compare the performance of the MiniBatchKMeans and KMeans: the MiniBatchKMeans is faster, but gives slightly different results (see *Mini Batch K-Means*).

We will cluster a set of data, first with KMeans and then with MiniBatchKMeans, and plot the results. We will also plot the points that are labelled differently between the two algorithms.

```

print(__doc__)

## 9.19 Compare BIRCH and MiniBatchKMeans

This example compares the timing of Birch (with and without the global clustering step) and MiniBatchKMeans on a synthetic dataset having 100,000 samples and 2 features generated using make\_blobs.

If n\_clusters is set to None, the data is reduced from 100,000 samples to a set of 158 clusters. This can be viewed as a preprocessing step before the final (global) clustering step that further reduces these 158 clusters to 100 clusters.

Out:

```
Birch without global clustering as the final step took 6.14 seconds
n_clusters : 158
Birch with global clustering as the final step took 6.16 seconds
n_clusters : 100
Time taken to run MiniBatchKMeans 5.57 seconds
```

```

## 9.20 Empirical evaluation of the impact of k-means initialization

Evaluate the ability of k-means initializations strategies to make the algorithm convergence robust as measured by the relative standard deviation of the inertia of the clustering (i.e. the sum of distances to the nearest cluster center).

The first plot shows the best inertia reached for each combination of the model (KMeans or MiniBatchKMeans) and the init method (`init="random"` or `init="kmeans++"`) for increasing values of the `n_init` parameter that controls the number of initializations.

The second plot demonstrate one single run of the MiniBatchKMeans estimator using a `init="random"` and `n_init=1`. This run leads to a bad convergence (local optimum) with estimated centers stuck between ground truth clusters.

The dataset used for evaluation is a 2D grid of isotropic Gaussian clusters widely spaced.

## 9.21 Adjustment for chance in clustering performance evaluation

The following plots demonstrate the impact of the number of clusters and number of samples on various clustering performance evaluation metrics.

Non-adjusted measures such as the V-Measure show a dependency between the number of clusters and the number of samples: the mean V-Measure of random labeling increases significantly as the number of clusters is closer to the total number of samples used to compute the measure.

Adjusted for chance measure such as ARI display some random variations centered around a mean score of 0.0 for any number of samples and clusters.

Only adjusted measures can hence safely be used as a consensus index to evaluate the average stability of clustering algorithms for a given value of  $k$  on various overlapping sub-samples of the dataset.

## 9.22 A demo of K-Means clustering on the handwritten digits data

In this example we compare the various initialization strategies for K-means in terms of runtime and quality of the results.

As the ground truth is known here, we also apply different cluster quality metrics to judge the goodness of fit of the cluster labels to the ground truth.

Cluster quality metrics evaluated (see [Clustering performance evaluation](#) for definitions and discussions of the metrics):

Shorthand	full name
homo	homogeneity score
compl	completeness score
v-meas	V measure
ARI	adjusted Rand index
AMI	adjusted mutual information
silhouette	silhouette coefficient

## 9.23 Selecting the number of clusters with silhouette analysis on KMeans clustering

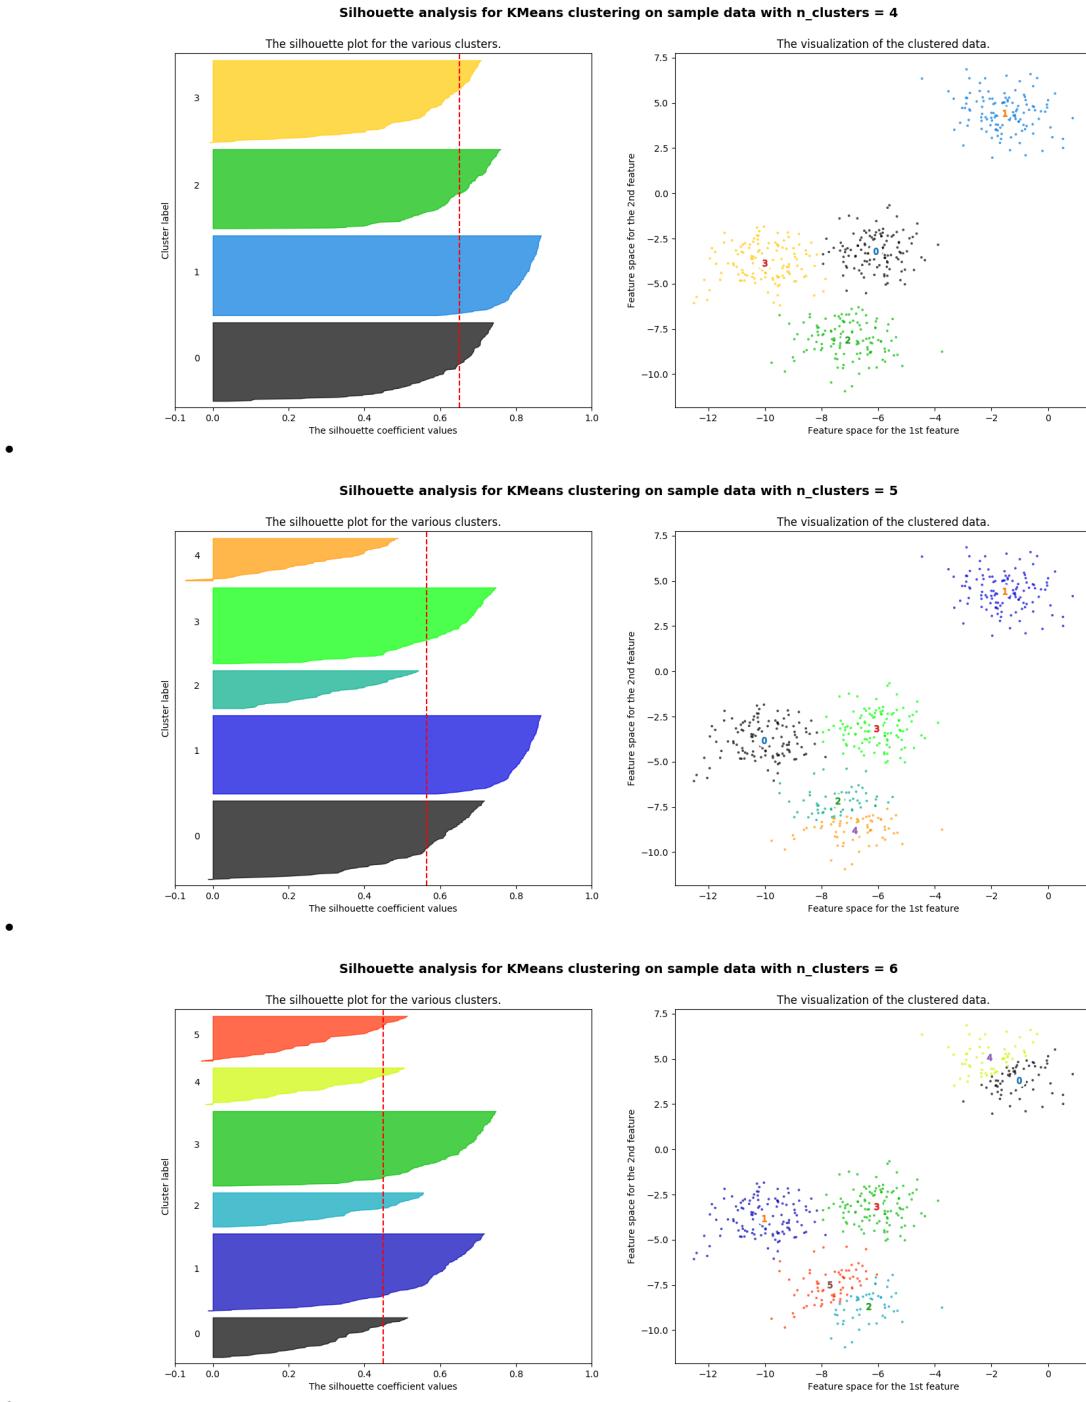

Silhouette analysis can be used to study the separation distance between the resulting clusters. The silhouette plot displays a measure of how close each point in one cluster is to points in the neighboring clusters and thus provides a way to assess parameters like number of clusters visually. This measure has a range of [-1, 1].

Silhouette coefficients (as these values are referred to as) near +1 indicate that the sample is far away from the neighboring clusters. A value of 0 indicates that the sample is on or very close to the decision boundary between two neighboring clusters and negative values indicate that those samples might have been assigned to the wrong cluster.

In this example the silhouette analysis is used to choose an optimal value for `n_clusters`. The silhouette plot shows that the `n_clusters` value of 3, 5 and 6 are a bad pick for the given data due to the presence of clusters with below average silhouette scores and also due to wide fluctuations in the size of the silhouette plots. Silhouette analysis is more ambivalent in deciding between 2 and 4.

Also from the thickness of the silhouette plot the cluster size can be visualized. The silhouette plot for cluster 0 when `n_clusters` is equal to 2, is bigger in size owing to the grouping of the 3 sub clusters into one big cluster. However when the `n_clusters` is equal to 4, all the plots are more or less of similar thickness and hence are of similar sizes as can be also verified from the labelled scatter plot on the right.

Out:

```
For n_clusters = 2 The average silhouette_score is : 0.704978749608
For n_clusters = 3 The average silhouette_score is : 0.588200401213
For n_clusters = 4 The average silhouette_score is : 0.650518663273
For n_clusters = 5 The average silhouette_score is : 0.563764690262
For n_clusters = 6 The average silhouette_score is : 0.450466629437
```

## 9.24 Comparing different clustering algorithms on toy datasets

This example shows characteristics of different clustering algorithms on datasets that are “interesting” but still in 2D. With the exception of the last dataset, the parameters of each of these dataset-algorithm pairs has been tuned to produce good clustering results. Some algorithms are more sensitive to parameter values than others.

The last dataset is an example of a ‘null’ situation for clustering: the data is homogeneous, and there is no good clustering. For this example, the null dataset uses the same parameters as the dataset in the row above it, which represents a mismatch in the parameter values and the data structure.

While these examples give some intuition about the algorithms, this intuition might not apply to very high dimensional data.

## COVARIANCE ESTIMATION

Examples concerning the `sklearn.covariance` module.

### 10.1 Ledoit-Wolf vs OAS estimation

The usual covariance maximum likelihood estimate can be regularized using shrinkage. Ledoit and Wolf proposed a close formula to compute the asymptotically optimal shrinkage parameter (minimizing a MSE criterion), yielding the Ledoit-Wolf covariance estimate.

Chen et al. proposed an improvement of the Ledoit-Wolf shrinkage parameter, the OAS coefficient, whose convergence is significantly better under the assumption that the data are Gaussian.

This example, inspired from Chen's publication [1], shows a comparison of the estimated MSE of the LW and OAS methods, using Gaussian distributed data.

[1] "Shrinkage Algorithms for MMSE Covariance Estimation" Chen et al., IEEE Trans. on Sign. Proc., Volume 58, Issue 10, October 2010.

## 10.2 Sparse inverse covariance estimation

Using the GraphLasso estimator to learn a covariance and sparse precision from a small number of samples.

To estimate a probabilistic model (e.g. a Gaussian model), estimating the precision matrix, that is the inverse covariance matrix, is as important as estimating the covariance matrix. Indeed a Gaussian model is parametrized by the precision matrix.

To be in favorable recovery conditions, we sample the data from a model with a sparse inverse covariance matrix. In addition, we ensure that the data is not too much correlated (limiting the largest coefficient of the precision matrix) and that there are no small coefficients in the precision matrix that cannot be recovered. In addition, with a small number of observations, it is easier to recover a correlation matrix rather than a covariance, thus we scale the time series.

Here, the number of samples is slightly larger than the number of dimensions, thus the empirical covariance is still invertible. However, as the observations are strongly correlated, the empirical covariance matrix is ill-conditioned and as a result its inverse –the empirical precision matrix– is very far from the ground truth.

If we use l2 shrinkage, as with the Ledoit-Wolf estimator, as the number of samples is small, we need to shrink a lot. As a result, the Ledoit-Wolf precision is fairly close to the ground truth precision, that is not far from being diagonal, but the off-diagonal structure is lost.

The l1-penalized estimator can recover part of this off-diagonal structure. It learns a sparse precision. It is not able to recover the exact sparsity pattern: it detects too many non-zero coefficients. However, the highest non-zero coefficients of the l1 estimated correspond to the non-zero coefficients in the ground truth. Finally, the coefficients of the l1 precision estimate are biased toward zero: because of the penalty, they are all smaller than the corresponding ground truth value, as can be seen on the figure.

Note that, the color range of the precision matrices is tweaked to improve readability of the figure. The full range of values of the empirical precision is not displayed.

The alpha parameter of the GraphLasso setting the sparsity of the model is set by internal cross-validation in the GraphLassoCV. As can be seen on figure 2, the grid to compute the cross-validation score is iteratively refined in the neighborhood of the maximum.

## 10.3 Shrinkage covariance estimation: LedoitWolf vs OAS and max-likelihood

When working with covariance estimation, the usual approach is to use a maximum likelihood estimator, such as the `sklearn.covariance.EmpiricalCovariance`. It is unbiased, i.e. it converges to the true (population) covariance when given many observations. However, it can also be beneficial to regularize it, in order to reduce its variance; this, in turn, introduces some bias. This example illustrates the simple regularization used in `ShrunkCovariance` estimators. In particular, it focuses on how to set the amount of regularization, i.e. how to choose the bias-variance trade-off.

Here we compare 3 approaches:

- Setting the parameter by cross-validating the likelihood on three folds according to a grid of potential shrinkage parameters.
- A close formula proposed by Ledoit and Wolf to compute the asymptotically optimal regularization parameter (minimizing a MSE criterion), yielding the `sklearn.covariance.LedoitWolf` covariance estimate.
- An improvement of the Ledoit-Wolf shrinkage, the `sklearn.covariance.OAS`, proposed by Chen et al. Its convergence is significantly better under the assumption that the data are Gaussian, in particular for small samples.

To quantify estimation error, we plot the likelihood of unseen data for different values of the shrinkage parameter. We also show the choices by cross-validation, or with the LedoitWolf and OAS estimates.

Note that the maximum likelihood estimate corresponds to no shrinkage, and thus performs poorly. The Ledoit-Wolf estimate performs really well, as it is close to the optimal and is computational not costly. In this example, the OAS estimate is a bit further away. Interestingly, both approaches outperform cross-validation, which is significantly more computationally costly.

```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from scipy import linalg

from sklearn.covariance import LedoitWolf, OAS, ShrunkCovariance, \
    log_likelihood, empirical_covariance
from sklearn.model_selection import GridSearchCV
```

Generate sample data

```

## 10.4 Robust covariance estimation and Mahalanobis distances relevance

An example to show covariance estimation with the Mahalanobis distances on Gaussian distributed data.

For Gaussian distributed data, the distance of an observation  $x_i$  to the mode of the distribution can be computed using its Mahalanobis distance:  $d_{(\mu, \Sigma)}(x_i)^2 = (x_i - \mu)' \Sigma^{-1} (x_i - \mu)$  where  $\mu$  and  $\Sigma$  are the location and the covariance of the underlying Gaussian distribution.

In practice,  $\mu$  and  $\Sigma$  are replaced by some estimates. The usual covariance maximum likelihood estimate is very sensitive to the presence of outliers in the data set and therefore, the corresponding Mahalanobis distances are. One would better have to use a robust estimator of covariance to guarantee that the estimation is resistant to “erroneous” observations in the data set and that the associated Mahalanobis distances accurately reflect the true organisation of the observations.

The Minimum Covariance Determinant estimator is a robust, high-breakdown point (i.e. it can be used to estimate the covariance matrix of highly contaminated datasets, up to  $\frac{n_{samples} - n_{features} - 1}{2}$  outliers) estimator of covariance. The idea is

to find  $\frac{n_{\text{samples}} + n_{\text{features}} + 1}{2}$  observations whose empirical covariance has the smallest determinant, yielding a “pure” subset of observations from which to compute standards estimates of location and covariance.

The Minimum Covariance Determinant estimator (MCD) has been introduced by P.J.Rousseeuw in [1].

This example illustrates how the Mahalanobis distances are affected by outlying data: observations drawn from a contaminating distribution are not distinguishable from the observations coming from the real, Gaussian distribution that one may want to work with. Using MCD-based Mahalanobis distances, the two populations become distinguishable. Associated applications are outliers detection, observations ranking, clustering, ... For visualization purpose, the cubic root of the Mahalanobis distances are represented in the boxplot, as Wilson and Hilderty suggest [2]

## 10.5 Outlier detection with several methods.

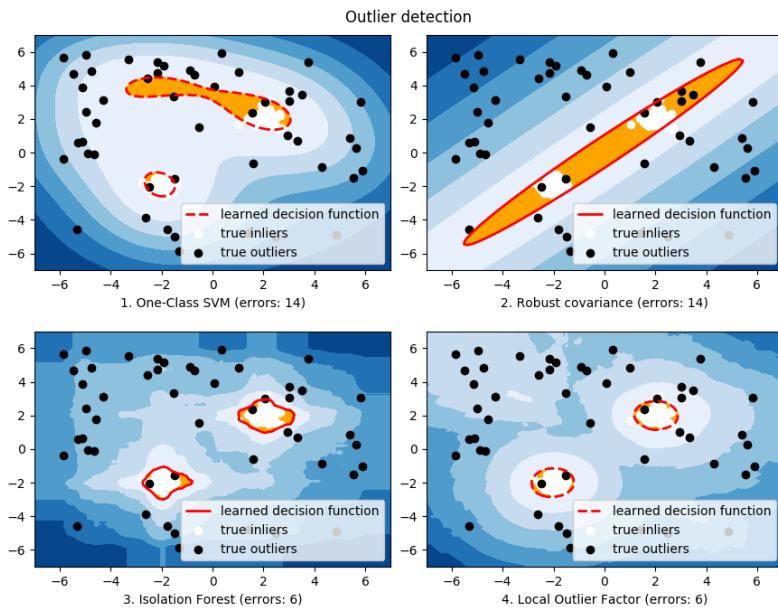

When the amount of contamination is known, this example illustrates three different ways of performing *Novelty and Outlier Detection*:

- based on a robust estimator of covariance, which is assuming that the data are Gaussian distributed and performs better than the One-Class SVM in that case.
- using the One-Class SVM and its ability to capture the shape of the data set, hence performing better when the data is strongly non-Gaussian, i.e. with two well-separated clusters;
- using the Isolation Forest algorithm, which is based on random forests and hence more adapted to large-dimensional settings, even if it performs quite well in the examples below.
- using the Local Outlier Factor to measure the local deviation of a given data point with respect to its neighbors by comparing their local density.

The ground truth about inliers and outliers is given by the points colors while the orange-filled area indicates which points are reported as inliers by each method.

Here, we assume that we know the fraction of outliers in the datasets. Thus rather than using the ‘predict’ method of the objects, we set the threshold on the decision\_function to separate out the corresponding fraction.

```

import numpy as np
from scipy import stats
import matplotlib.pyplot as plt
import matplotlib.font_manager

from sklearn import svm
from sklearn.covariance import EllipticEnvelope
from sklearn.ensemble import IsolationForest
from sklearn.neighbors import LocalOutlierFactor

## 10.6 Robust vs Empirical covariance estimate

The usual covariance maximum likelihood estimate is very sensitive to the presence of outliers in the data set. In such a case, it would be better to use a robust estimator of covariance to guarantee that the estimation is resistant to “erroneous” observations in the data set.

### 10.6.1 Minimum Covariance Determinant Estimator

The Minimum Covariance Determinant estimator is a robust, high-breakdown point (i.e. it can be used to estimate the covariance matrix of highly contaminated datasets, up to  $\frac{n_{\text{samples}} - n_{\text{features}} - 1}{2}$  outliers) estimator of covariance. The idea is to find  $\frac{n_{\text{samples}} + n_{\text{features}} + 1}{2}$  observations whose empirical covariance has the smallest determinant, yielding a “pure” subset of observations from which to compute standards estimates of location and covariance. After a correction step aiming at compensating the fact that the estimates were learned from only a portion of the initial data, we end up with robust estimates of the data set location and covariance.

The Minimum Covariance Determinant estimator (MCD) has been introduced by P.J.Rousseeuw in<sup>1</sup>.

### 10.6.2 Evaluation

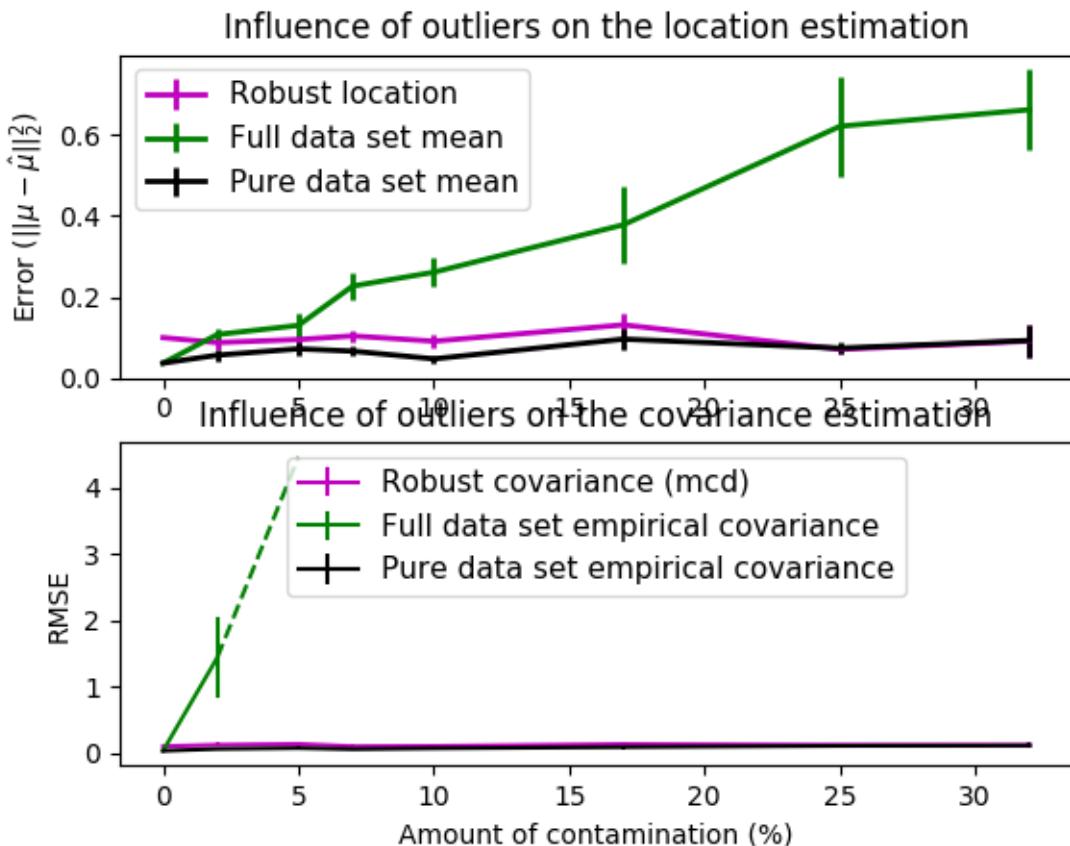

In this example, we compare the estimation errors that are made when using various types of location and covariance estimates on contaminated Gaussian distributed data sets:

- The mean and the empirical covariance of the full dataset, which break down as soon as there are outliers in the data set
- The robust MCD, that has a low error provided  $n_{\text{samples}} > 5n_{\text{features}}$
- The mean and the empirical covariance of the observations that are known to be good ones. This can be considered as a “perfect” MCD estimation, so one can trust our implementation by comparing to this case.

---

## CROSS DECOMPOSITION

Examples concerning the `sklearn.cross_decomposition` module.

### 11.1 Compare cross decomposition methods

Simple usage of various cross decomposition algorithms: - PLSCanonical - PLSRegression, with multivariate response, a.k.a. PLS2 - PLSRegression, with univariate response, a.k.a. PLS1 - CCA

Given 2 multivariate covarying two-dimensional datasets, X, and Y, PLS extracts the ‘directions of covariance’, i.e. the components of each datasets that explain the most shared variance between both datasets. This is apparent on the **scatterplot matrix** display: components 1 in dataset X and dataset Y are maximally correlated (points lie around the first diagonal). This is also true for components 2 in both dataset, however, the correlation across datasets for different components is weak: the point cloud is very spherical.

```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from sklearn.cross_decomposition import PLSCanonical, PLSRegression, CCA
```

Dataset based latent variables model

```
n = 500
# 2 latents vars:
l1 = np.random.normal(size=n)
l2 = np.random.normal(size=n)

latents = np.array([l1, l1, l2, l2]).T
X = latents + np.random.normal(size=4 * n).reshape((n, 4))
Y = latents + np.random.normal(size=4 * n).reshape((n, 4))

X_train = X[:n // 2]
Y_train = Y[:n // 2]
X_test = X[n // 2:]
Y_test = Y[n // 2:]

print("Corr(X)")
print(np.round(np.corrcoef(X.T), 2))
print("Corr(Y)")
print(np.round(np.corrcoef(Y.T), 2))
```

Out:

```

Corr(X)
[[ 1.    0.52 -0.03  0.   ]
 [ 0.52  1.    0.02 -0.01]
 [-0.03  0.02  1.    0.45]
 [ 0.    -0.01  0.45  1.   ]]
Corr(Y)

## DATASET EXAMPLES

Examples concerning the `sklearn.datasets` module.

### 12.1 The Digit Dataset

This dataset is made up of 1797 8x8 images. Each image, like the one shown below, is of a hand-written digit. In order to utilize an 8x8 figure like this, we'd have to first transform it into a feature vector with length 64.

See [here](#) for more information about this dataset.

```
print(__doc__)

# Code source: Gaël Varoquaux
# Modified for documentation by Jaques Grobler
# License: BSD 3 clause

from sklearn import datasets

import matplotlib.pyplot as plt

#Load the digits dataset
digits = datasets.load_digits()
```

```
#Display the first digit
plt.figure(1, figsize=(3, 3))
plt.imshow(digits.images[-1], cmap=plt.cm.gray_r, interpolation='nearest')
plt.show()
```

**Total running time of the script:** ( 0 minutes 0.263 seconds)

## 12.2 The Iris Dataset

This data sets consists of 3 different types of irises' (Setosa, Versicolour, and Virginica) petal and sepal length, stored in a 150x4 numpy.ndarray

The rows being the samples and the columns being: Sepal Length, Sepal Width, Petal Length and Petal Width.

The below plot uses the first two features. See [here](#) for more information on this dataset.

```

print(__doc__)

# Code source: Gaël Varoquaux
# Modified for documentation by Jaques Grobler
# License: BSD 3 clause

import matplotlib.pyplot as plt
from mpl_toolkits.mplot3d import Axes3D
from sklearn import datasets
from sklearn.decomposition import PCA

# import some data to play with
iris = datasets.load_iris()
X = iris.data[:, :2] # we only take the first two features.
y = iris.target

x_min, x_max = X[:, 0].min() - .5, X[:, 0].max() + .5
y_min, y_max = X[:, 1].min() - .5, X[:, 1].max() + .5

plt.figure(2, figsize=(8, 6))
plt.clf()

# Plot the training points
plt.scatter(X[:, 0], X[:, 1], c=y, cmap=plt.cm.Paired)
plt.xlabel('Sepal length')
plt.ylabel('Sepal width')

plt.xlim(x_min, x_max)
plt.ylim(y_min, y_max)
plt.xticks(())
plt.yticks(())

# To get a better understanding of interaction of the dimensions
# plot the first three PCA dimensions
fig = plt.figure(1, figsize=(8, 6))
ax = Axes3D(fig, elev=-150, azim=110)
X_reduced = PCA(n_components=3).fit_transform(iris.data)
ax.scatter(X_reduced[:, 0], X_reduced[:, 1], X_reduced[:, 2], c=y,
          s=40, edgecolor='k')

```

```
cmap=plt.cm.Paired)
ax.set_title("First three PCA directions")
ax.set_xlabel("1st eigenvector")
ax.w_xaxis.set_ticklabels([])
ax.set_ylabel("2nd eigenvector")
ax.w_yaxis.set_ticklabels([])
ax.set_zlabel("3rd eigenvector")
ax.w_zaxis.set_ticklabels([])

plt.show()

## 12.4 Plot randomly generated multilabel dataset

This illustrates the `datasets.make_multilabel_classification` dataset generator. Each sample consists of counts of two features (up to 50 in total), which are differently distributed in each of two classes.

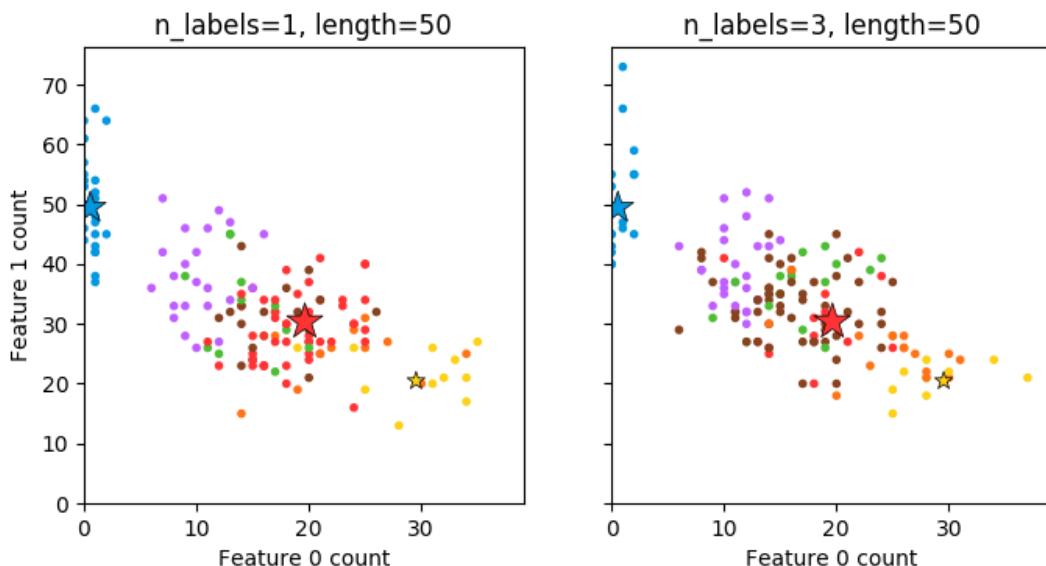

Points are labeled as follows, where Y means the class is present:

1	2	3	Color
Y	N	N	Red
N	Y	N	Blue
N	N	Y	Yellow
Y	Y	N	Purple
Y	N	Y	Orange
Y	Y	N	Green
Y	Y	Y	Brown

A star marks the expected sample for each class; its size reflects the probability of selecting that class label.

The left and right examples highlight the `n_labels` parameter: more of the samples in the right plot have 2 or 3 labels.

Note that this two-dimensional example is very degenerate: generally the number of features would be much greater than the “document length”, while here we have much larger documents than vocabulary. Similarly, with `n_classes > n_features`, it is much less likely that a feature distinguishes a particular class.

Out:

```
The data was generated from (random_state=54):
Class    P(C)      P(w0|C)  P(w1|C)
red      0.43      0.39     0.61
blue     0.38      0.01     0.99
yellow   0.19      0.59     0.41
```

```
from __future__ import print_function
import numpy as np

## 13.3 Incremental PCA

Incremental principal component analysis (IPCA) is typically used as a replacement for principal component analysis (PCA) when the dataset to be decomposed is too large to fit in memory. IPCA builds a low-rank approximation for the input data using an amount of memory which is independent of the number of input data samples. It is still dependent on the input data features, but changing the batch size allows for control of memory usage.

This example serves as a visual check that IPCA is able to find a similar projection of the data to PCA (to a sign flip), while only processing a few samples at a time. This can be considered a “toy example”, as IPCA is intended for large datasets which do not fit in main memory, requiring incremental approaches.

```
print(__doc__)

# Authors: Kyle Kastner
# License: BSD 3 clause
```

```

import numpy as np
import matplotlib.pyplot as plt

from sklearn.datasets import load_iris
from sklearn.decomposition import PCA, IncrementalPCA

iris = load_iris()

## 13.4 Comparison of LDA and PCA 2D projection of Iris dataset

The Iris dataset represents 3 kind of Iris flowers (Setosa, Versicolour and Virginica) with 4 attributes: sepal length, sepal width, petal length and petal width.

Principal Component Analysis (PCA) applied to this data identifies the combination of attributes (principal components, or directions in the feature space) that account for the most variance in the data. Here we plot the different samples on the 2 first principal components.

Linear Discriminant Analysis (LDA) tries to identify attributes that account for the most variance *between classes*. In particular, LDA, in contrast to PCA, is a supervised method, using known class labels.

Out:

```
explained variance ratio (first two components): [ 0.92461621  0.05301557]
```

```
print(__doc__)

import matplotlib.pyplot as plt

from sklearn import datasets
from sklearn.decomposition import PCA
from sklearn.discriminant_analysis import LinearDiscriminantAnalysis

iris = datasets.load_iris()

X = iris.data
y = iris.target
target_names = iris.target_names

pca = PCA(n_components=2)
X_r = pca.fit(X).transform(X)

lda = LinearDiscriminantAnalysis(n_components=2)
```

```

X_r2 = lda.fit(X, y).transform(X)

# Percentage of variance explained for each components
print('explained variance ratio (first two components): %s'
      % str(pca.explained_variance_ratio_))

plt.figure()

## 13.5 Blind source separation using FastICA

An example of estimating sources from noisy data.

*Independent component analysis (ICA)* is used to estimate sources given noisy measurements. Imagine 3 instruments playing simultaneously and 3 microphones recording the mixed signals. ICA is used to recover the sources ie. what is played by each instrument. Importantly, PCA fails at recovering our *instruments* since the related signals reflect non-Gaussian processes.

```

print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from scipy import signal

from sklearn.decomposition import FastICA, PCA

```

Generate sample data

```

np.random.seed(0)
n_samples = 2000
time = np.linspace(0, 8, n_samples)

s1 = np.sin(2 * time) # Signal 1 : sinusoidal signal

```

```

s2 = np.sign(np.sin(3 * time)) # Signal 2 : square signal
s3 = signal.sawtooth(2 * np.pi * time) # Signal 3: saw tooth signal

S = np.c_[s1, s2, s3]
S += 0.2 * np.random.normal(size=S.shape) # Add noise

S /= S.std(axis=0) # Standardize data
# Mix data
A = np.array([[1, 1, 1], [0.5, 2, 1.0], [1.5, 1.0, 2.0]]) # Mixing matrix
X = np.dot(S, A.T) # Generate observations

# Compute ICA
ica = FastICA(n_components=3)
S_ = ica.fit_transform(X) # Reconstruct signals
A_ = ica.mixing_ # Get estimated mixing matrix

# We can `prove` that the ICA model applies by reverting the unmixing.
assert np.allclose(X, np.dot(S_, A_.T) + ica.mean_)

# For comparison, compute PCA
pca = PCA(n_components=3)
H = pca.fit_transform(X) # Reconstruct signals based on orthogonal components

```

Plot results

```

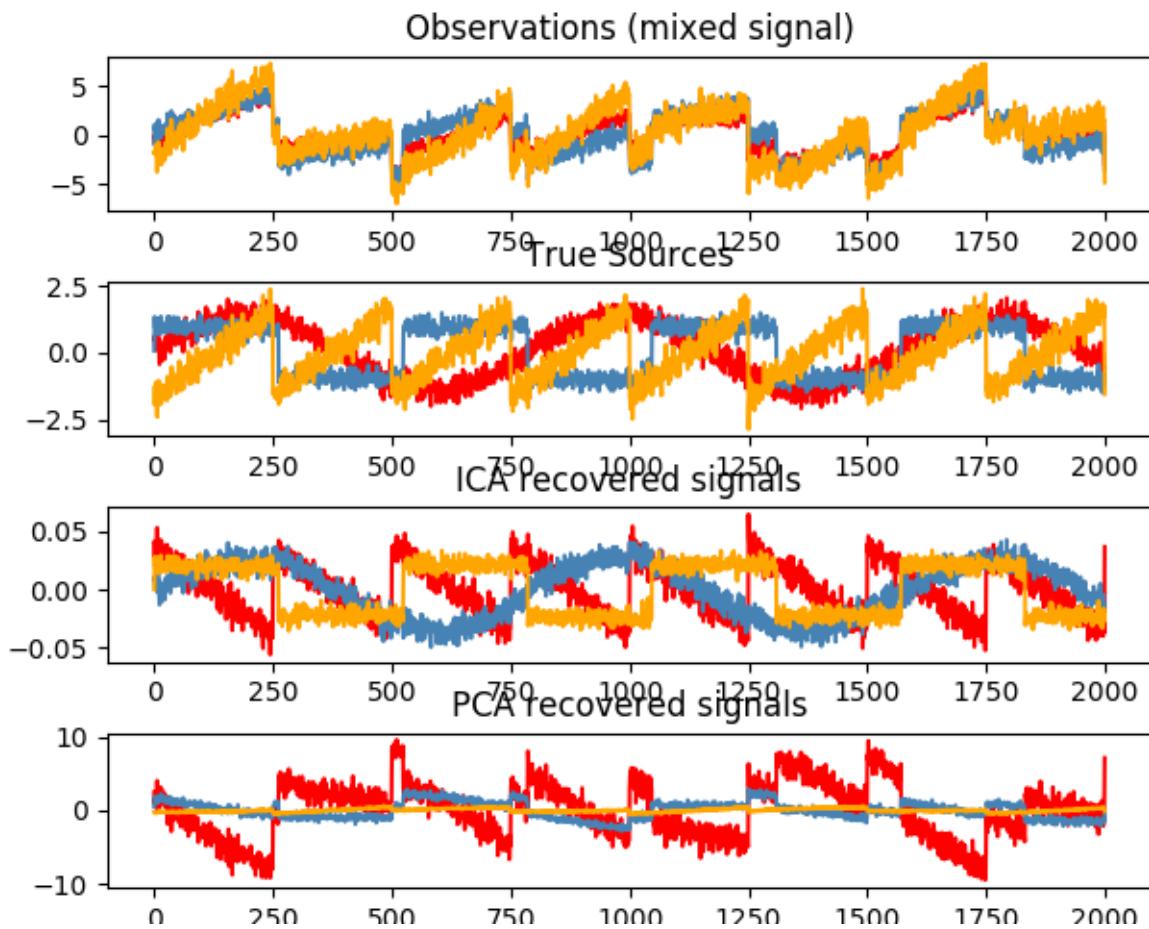

plt.figure()

models = [X, S, S_, H]
names = ['Observations (mixed signal)',
         'True Sources',
         'ICA recovered signals',
         'PCA recovered signals']
colors = ['red', 'steelblue', 'orange']

for ii, (model, name) in enumerate(zip(models, names), 1):
    plt.subplot(4, 1, ii)
    plt.title(name)
    for sig, color in zip(model.T, colors):
        plt.plot(sig, color=color)

plt.subplots_adjust(0.09, 0.04, 0.94, 0.94, 0.26, 0.46)
plt.show()

```

## 13.6 FastICA on 2D point clouds

This example illustrates visually in the feature space a comparison by results using two different component analysis techniques.

*Independent component analysis (ICA) vs Principal component analysis (PCA).*

Representing ICA in the feature space gives the view of ‘geometric ICA’: ICA is an algorithm that finds directions in the feature space corresponding to projections with high non-Gaussianity. These directions need not be orthogonal in the original feature space, but they are orthogonal in the whitened feature space, in which all directions correspond to the same variance.

PCA, on the other hand, finds orthogonal directions in the raw feature space that correspond to directions accounting for maximum variance.

Here we simulate independent sources using a highly non-Gaussian process, 2 student T with a low number of degrees of freedom (top left figure). We mix them to create observations (top right figure). In this raw observation space, directions identified by PCA are represented by orange vectors. We represent the signal in the PCA space, after

whitening by the variance corresponding to the PCA vectors (lower left). Running ICA corresponds to finding a rotation in this space to identify the directions of largest non-Gaussianity (lower right).

```

## 13.9 Model selection with Probabilistic PCA and Factor Analysis (FA)

Probabilistic PCA and Factor Analysis are probabilistic models. The consequence is that the likelihood of new data can be used for model selection and covariance estimation. Here we compare PCA and FA with cross-validation on low rank data corrupted with homoscedastic noise (noise variance is the same for each feature) or heteroscedastic noise (noise variance is the different for each feature). In a second step we compare the model likelihood to the likelihoods obtained from shrinkage covariance estimators.

One can observe that with homoscedastic noise both FA and PCA succeed in recovering the size of the low rank subspace. The likelihood with PCA is higher than FA in this case. However PCA fails and overestimates the rank when heteroscedastic noise is present. Under appropriate circumstances the low rank models are more likely than shrinkage models.

The automatic estimation from Automatic Choice of Dimensionality for PCA. NIPS 2000: 598-604 by Thomas P. Minka is also compared.

## 13.10 Sparse coding with a precomputed dictionary

Transform a signal as a sparse combination of Ricker wavelets. This example visually compares different sparse coding methods using the `sklearn.decomposition.SparseCoder` estimator. The Ricker (also known as Mexican hat or the second derivative of a Gaussian) is not a particularly good kernel to represent piecewise constant signals like this one. It can therefore be seen how much adding different widths of atoms matters and it therefore motivates learning the dictionary to best fit your type of signals.

The richer dictionary on the right is not larger in size, heavier subsampling is performed in order to stay on the same order of magnitude.

```

print(__doc__)

import numpy as np
import matplotlib.pyplot as plt

from sklearn.decomposition import SparseCoder

def ricker_function(resolution, center, width):
    """Discrete sub-sampled Ricker (Mexican hat) wavelet"""
    x = np.linspace(0, resolution - 1, resolution)

## 13.12 Image denoising using dictionary learning

An example comparing the effect of reconstructing noisy fragments of a raccoon face image using firstly online *Dictionary Learning* and various transform methods.

The dictionary is fitted on the distorted left half of the image, and subsequently used to reconstruct the right half. Note that even better performance could be achieved by fitting to an undistorted (i.e. noiseless) image, but here we start from the assumption that it is not available.

A common practice for evaluating the results of image denoising is by looking at the difference between the reconstruction and the original image. If the reconstruction is perfect this will look like Gaussian noise.

It can be seen from the plots that the results of *Orthogonal Matching Pursuit (OMP)* with two non-zero coefficients is a bit less biased than when keeping only one (the edges look less prominent). It is in addition closer from the ground truth in Frobenius norm.

The result of *Least Angle Regression* is much more strongly biased: the difference is reminiscent of the local intensity value of the original image.

Thresholding is clearly not useful for denoising, but it is here to show that it can produce a suggestive output with very high speed, and thus be useful for other tasks such as object classification, where performance is not necessarily related to visualisation.

```

## ENSEMBLE METHODS

Examples concerning the `sklearn.ensemble` module.

### 14.1 Decision Tree Regression with AdaBoost

A decision tree is boosted using the AdaBoost.R2 [1] algorithm on a 1D sinusoidal dataset with a small amount of Gaussian noise. 299 boosts (300 decision trees) is compared with a single decision tree regressor. As the number of boosts is increased the regressor can fit more detail.

## 14.3 IsolationForest example

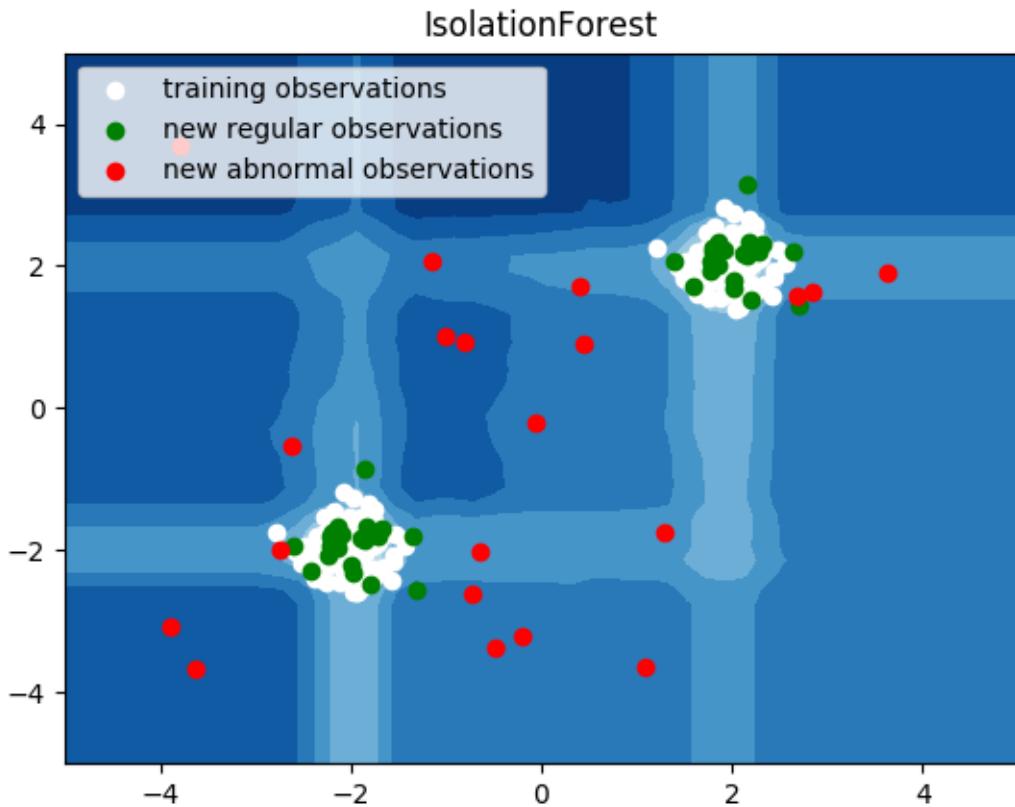

An example using IsolationForest for anomaly detection.

The IsolationForest ‘isolates’ observations by randomly selecting a feature and then randomly selecting a split value between the maximum and minimum values of the selected feature.

Since recursive partitioning can be represented by a tree structure, the number of splittings required to isolate a sample is equivalent to the path length from the root node to the terminating node.

This path length, averaged over a forest of such random trees, is a measure of normality and our decision function.

Random partitioning produces noticeable shorter paths for anomalies. Hence, when a forest of random trees collectively produce shorter path lengths for particular samples, they are highly likely to be anomalies.

```

print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from sklearn.ensemble import IsolationForest

rng = np.random.RandomState(42)

# Generate train data
X = 0.3 * rng.randn(100, 2)
X_train = np.r_[X + 2, X - 2]
# Generate some regular novel observations
X = 0.3 * rng.randn(20, 2)
X_test = np.r_[X + 2, X - 2]
# Generate some abnormal novel observations
X_outliers = rng.uniform(low=-4, high=4, size=(20, 2))

# fit the model
clf = IsolationForest(max_samples=100, random_state=rng)
clf.fit(X_train)

y_pred_train = clf.predict(X_train)
y_pred_test = clf.predict(X_test)
y_pred_outliers = clf.predict(X_outliers)

# plot the line, the samples, and the nearest vectors to the plane
xx, yy = np.meshgrid(np.linspace(-5, 5, 50), np.linspace(-5, 5, 50))

```

```
Z = clf.decision_function(np.c_[xx.ravel(), yy.ravel()])
Z = Z.reshape(xx.shape)

plt.title("IsolationForest")
plt.contourf(xx, yy, Z, cmap=plt.cm.Blues_r)

## 14.6 Comparing random forests and the multi-output meta estimator

An example to compare multi-output regression with random forest and the `multioutput.MultiOutputRegressor` meta-estimator.

This example illustrates the use of the `multioutput.MultiOutputRegressor` meta-estimator to perform multi-output regression. A random forest regressor is used, which supports multi-output regression natively, so the results can be compared.

The random forest regressor will only ever predict values within the range of observations or closer to zero for each of the targets. As a result the predictions are biased towards the centre of the circle.

Using a single underlying feature the model learns both the x and y coordinate as output.

```

## 14.9 Plot class probabilities calculated by the VotingClassifier

Plot the class probabilities of the first sample in a toy dataset predicted by three different classifiers and averaged by the *VotingClassifier*.

First, three exemplary classifiers are initialized (*LogisticRegression*, *GaussianNB*, and *RandomForestClassifier*) and used to initialize a soft-voting *VotingClassifier* with weights [1, 1, 5], which means that the predicted probabilities of the *RandomForestClassifier* count 5 times as much as the weights of the other classifiers when the averaged probability is calculated.

To visualize the probability weighting, we fit each classifier on the training set and plot the predicted class probabilities for the first sample in this example dataset.

```

## 14.10 Gradient Boosting regularization

Illustration of the effect of different regularization strategies for Gradient Boosting. The example is taken from Hastie et al 2009.

The loss function used is binomial deviance. Regularization via shrinkage (`learning_rate < 1.0`) improves performance considerably. In combination with shrinkage, stochastic gradient boosting (`subsample < 1.0`) can produce more accurate models by reducing the variance via bagging. Subsampling without shrinkage usually does

poorly. Another strategy to reduce the variance is by subsampling the features analogous to the random splits in Random Forests (via the `max_features` parameter).

## 14.11 OOB Errors for Random Forests

The `RandomForestClassifier` is trained using *bootstrap aggregation*, where each new tree is fit from a bootstrap sample of the training observations  $z_i = (x_i, y_i)$ . The *out-of-bag* (OOB) error is the average error for each  $z_i$  calculated using predictions from the trees that do not contain  $z_i$  in their respective bootstrap sample. This allows the `RandomForestClassifier` to be fit and validated whilst being trained [1].

The example below demonstrates how the OOB error can be measured at the addition of each new tree during training. The resulting plot allows a practitioner to approximate a suitable value of `n_estimators` at which the error stabilizes.

```

import matplotlib.pyplot as plt

from collections import OrderedDict
from sklearn.datasets import make_classification
from sklearn.ensemble import RandomForestClassifier, ExtraTreesClassifier

# Author: Kian Ho <hui.kian.ho@gmail.com>

## 14.12 Two-class AdaBoost

This example fits an AdaBoosted decision stump on a non-linearly separable classification dataset composed of two “Gaussian quantiles” clusters (see `sklearn.datasets.make_gaussian_quantiles`) and plots the decision boundary and decision scores. The distributions of decision scores are shown separately for samples of class A and B. The predicted class label for each sample is determined by the sign of the decision score. Samples with decision scores greater than zero are classified as B, and are otherwise classified as A. The magnitude of a decision score determines the degree of likeness with the predicted class label. Additionally, a new dataset could be constructed containing a

desired purity of class B, for example, by only selecting samples with a decision score above some value.

## 14.13 Hashing feature transformation using Totally Random Trees

RandomTreesEmbedding provides a way to map data to a very high-dimensional, sparse representation, which might be beneficial for classification. The mapping is completely unsupervised and very efficient.

This example visualizes the partitions given by several trees and shows how the transformation can also be used for non-linear dimensionality reduction or non-linear classification.

Points that are neighboring often share the same leaf of a tree and therefore share large parts of their hashed representation. This allows to separate two concentric circles simply based on the principal components of the transformed data with truncated SVD.

In high-dimensional spaces, linear classifiers often achieve excellent accuracy. For sparse binary data, BernoulliNB is particularly well-suited. The bottom row compares the decision boundary obtained by BernoulliNB in the transformed space with an ExtraTreesClassifier forests learned on the original data.

```
import numpy as np
import matplotlib.pyplot as plt

from sklearn.datasets import make_circles
```

```

from sklearn.ensemble import RandomTreesEmbedding, ExtraTreesClassifier
from sklearn.decomposition import TruncatedSVD
from sklearn.naive_bayes import BernoulliNB

# make a synthetic dataset

## 14.14 Partial Dependence Plots

Partial dependence plots show the dependence between the target function<sup>2</sup> and a set of ‘target’ features, marginalizing over the values of all other features (the complement features). Due to the limits of human perception the size of the target feature set must be small (usually, one or two) thus the target features are usually chosen among the most important features (see [feature\\_importances\\_](#)).

This example shows how to obtain partial dependence plots from a [GradientBoostingRegressor](#) trained on the California housing dataset. The example is taken from<sup>1</sup>.

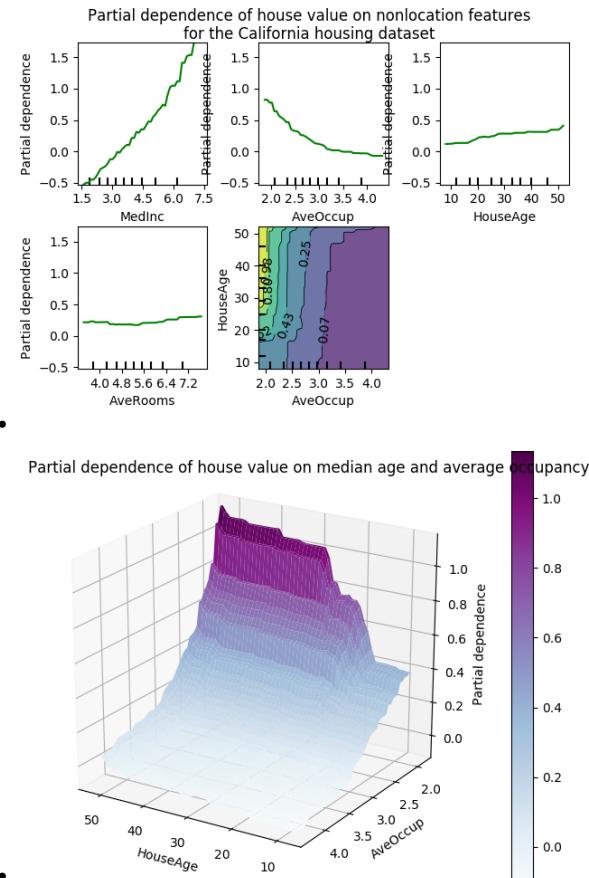

The plot shows four one-way and one two-way partial dependence plots. The target variables for the one-way PDP are: median income (*MedInc*), avg. occupants per household (*AvgOccup*), median house age (*HouseAge*), and avg. rooms per household (*AveRooms*).

We can clearly see that the median house price shows a linear relationship with the median income (top left) and that the house price drops when the avg. occupants per household increases (top middle). The top right plot shows that the house age in a district does not have a strong influence on the (median) house price; so does the average rooms per household. The tick marks on the x-axis represent the deciles of the feature values in the training data.

Partial dependence plots with two target features enable us to visualize interactions among them. The two-way partial dependence plot shows the dependence of median house price on joint values of house age and avg. occupants per household. We can clearly see an interaction between the two features: For an avg. occupancy greater than two, the house price is nearly independent of the house age, whereas for values less than two there is a strong dependence on age.

<sup>2</sup> For classification you can think of it as the regression score before the link function.

## 14.15 Discrete versus Real AdaBoost

This example is based on Figure 10.2 from Hastie et al 2009 [1] and illustrates the difference in performance between the discrete SAMME [2] boosting algorithm and real SAMME.R boosting algorithm. Both algorithms are evaluated on a binary classification task where the target Y is a non-linear function of 10 input features.

Discrete SAMME AdaBoost adapts based on errors in predicted class labels whereas real SAMME.R uses the predicted class probabilities.

## 14.16 Multi-class AdaBoosted Decision Trees

This example reproduces Figure 1 of Zhu et al [1] and shows how boosting can improve prediction accuracy on a multi-class problem. The classification dataset is constructed by taking a ten-dimensional standard normal distribution and defining three classes separated by nested concentric ten-dimensional spheres such that roughly equal numbers of samples are in each class (quantiles of the  $\chi^2$  distribution).

The performance of the SAMME and SAMME.R [1] algorithms are compared. SAMME.R uses the probability estimates to update the additive model, while SAMME uses the classifications only. As the example illustrates, the SAMME.R algorithm typically converges faster than SAMME, achieving a lower test error with fewer boosting iterations. The error of each algorithm on the test set after each boosting iteration is shown on the left, the classification error on the test set of each tree is shown in the middle, and the boost weight of each tree is shown on the right. All trees have a weight of one in the SAMME.R algorithm and therefore are not shown.

## 14.17 Feature transformations with ensembles of trees

Transform your features into a higher dimensional, sparse space. Then train a linear model on these features.

First fit an ensemble of trees (totally random trees, a random forest, or gradient boosted trees) on the training set. Then each leaf of each tree in the ensemble is assigned a fixed arbitrary feature index in a new feature space. These leaf indices are then encoded in a one-hot fashion.

Each sample goes through the decisions of each tree of the ensemble and ends up in one leaf per tree. The sample is encoded by setting feature values for these leaves to 1 and the other feature values to 0.

The resulting transformer has then learned a supervised, sparse, high-dimensional categorical embedding of the data.

## 14.18 Gradient Boosting Out-of-Bag estimates

Out-of-bag (OOB) estimates can be a useful heuristic to estimate the “optimal” number of boosting iterations. OOB estimates are almost identical to cross-validation estimates but they can be computed on-the-fly without the need for repeated model fitting. OOB estimates are only available for Stochastic Gradient Boosting (i.e. `subsample < 1.0`), the estimates are derived from the improvement in loss based on the examples not included in the bootstrap sample (the so-called out-of-bag examples). The OOB estimator is a pessimistic estimator of the true test loss, but remains a fairly good approximation for a small number of trees.

The figure shows the cumulative sum of the negative OOB improvements as a function of the boosting iteration. As you can see, it tracks the test loss for the first hundred iterations but then diverges in a pessimistic way. The figure also shows the performance of 3-fold cross validation which usually gives a better estimate of the test loss but is computationally more demanding.

## 14.19 Single estimator versus bagging: bias-variance decomposition

This example illustrates and compares the bias-variance decomposition of the expected mean squared error of a single estimator against a bagging ensemble.

In regression, the expected mean squared error of an estimator can be decomposed in terms of bias, variance and noise. On average over datasets of the regression problem, the bias term measures the average amount by which the predictions of the estimator differ from the predictions of the best possible estimator for the problem (i.e., the Bayes model). The variance term measures the variability of the predictions of the estimator when fit over different instances LS of the problem. Finally, the noise measures the irreducible part of the error which is due the variability in the data.

The upper left figure illustrates the predictions (in dark red) of a single decision tree trained over a random dataset LS

(the blue dots) of a toy 1d regression problem. It also illustrates the predictions (in light red) of other single decision trees trained over other (and different) randomly drawn instances LS of the problem. Intuitively, the variance term here corresponds to the width of the beam of predictions (in light red) of the individual estimators. The larger the variance, the more sensitive are the predictions for  $x$  to small changes in the training set. The bias term corresponds to the difference between the average prediction of the estimator (in cyan) and the best possible model (in dark blue). On this problem, we can thus observe that the bias is quite low (both the cyan and the blue curves are close to each other) while the variance is large (the red beam is rather wide).

The lower left figure plots the pointwise decomposition of the expected mean squared error of a single decision tree. It confirms that the bias term (in blue) is low while the variance is large (in green). It also illustrates the noise part of the error which, as expected, appears to be constant and around 0.01.

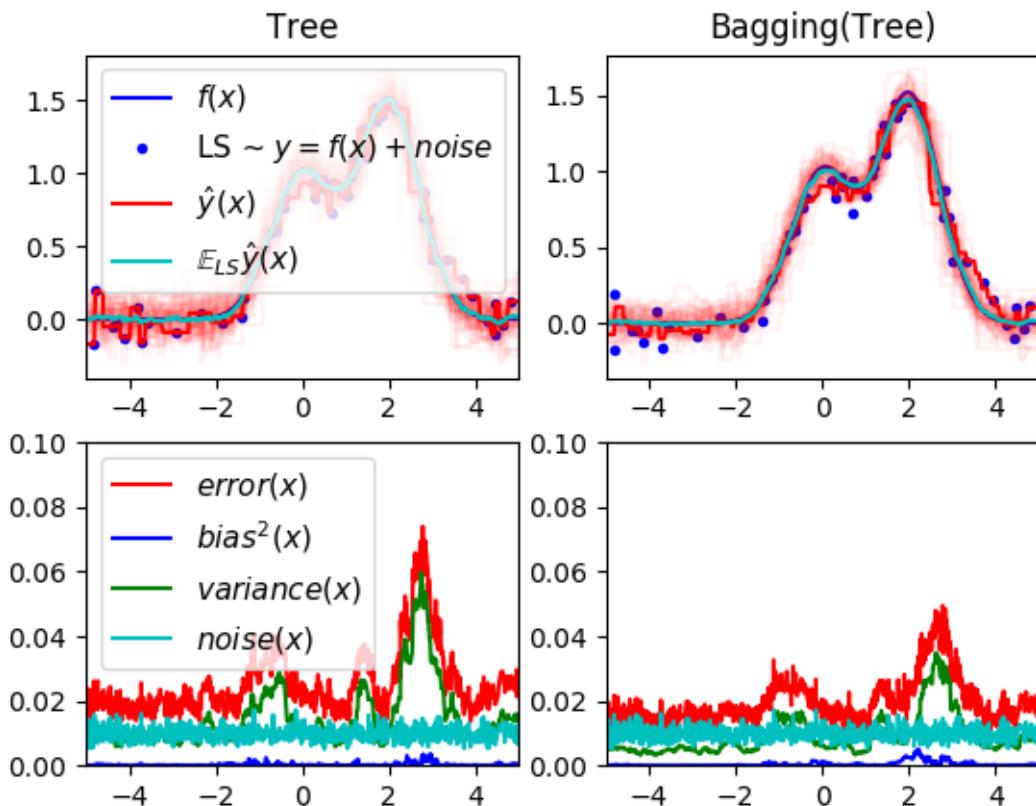

The right figures correspond to the same plots but using instead a bagging ensemble of decision trees. In both figures, we can observe that the bias term is larger than in the previous case. In the upper right figure, the difference between the average prediction (in cyan) and the best possible model is larger (e.g., notice the offset around  $x=2$ ). In the lower right figure, the bias curve is also slightly higher than in the lower left figure. In terms of variance however, the beam of predictions is narrower, which suggests that the variance is lower. Indeed, as the lower right figure confirms, the variance term (in green) is lower than for single decision trees. Overall, the bias-variance decomposition is therefore no longer the same. The tradeoff is better for bagging: averaging several decision trees fit on bootstrap copies of the dataset slightly increases the bias term but allows for a larger reduction of the variance, which results in a lower overall mean squared error (compare the red curves in the lower figures). The script output also confirms this intuition. The total error of the bagging ensemble is lower than the total error of a single decision tree, and this difference indeed mainly stems from a reduced variance.

For further details on bias-variance decomposition, see section 7.3 of<sup>1</sup>.

## 14.20 Plot the decision surfaces of ensembles of trees on the iris dataset

Plot the decision surfaces of forests of randomized trees trained on pairs of features of the iris dataset.

This plot compares the decision surfaces learned by a decision tree classifier (first column), by a random forest classifier (second column), by an extra- trees classifier (third column) and by an AdaBoost classifier (fourth column).

In the first row, the classifiers are built using the sepal width and the sepal length features only, on the second row using the petal length and sepal length only, and on the third row using the petal width and the petal length only.

In descending order of quality, when trained (outside of this example) on all 4 features using 30 estimators and scored using 10 fold cross validation, we see:

```
ExtraTreesClassifier() # 0.95 score
RandomForestClassifier() # 0.94 score
AdaBoost(DecisionTree(max_depth=3)) # 0.94 score
DecisionTree(max_depth=None) # 0.94 score
```

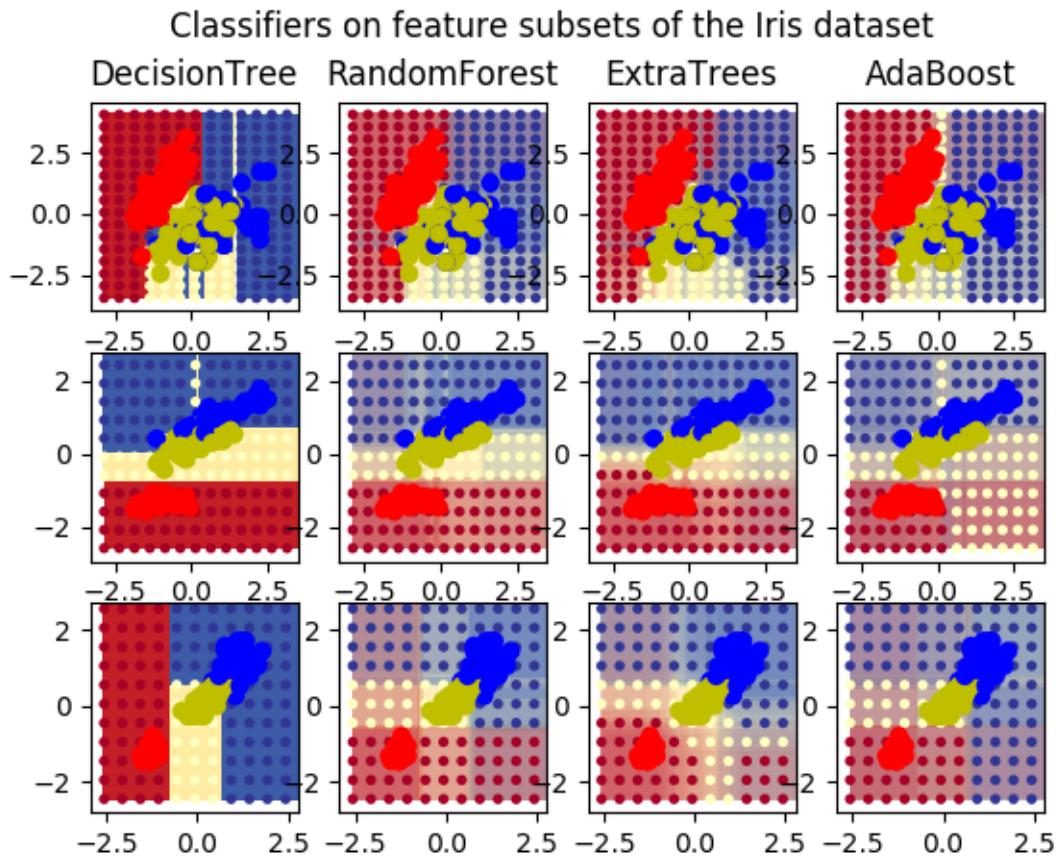

Increasing `max_depth` for AdaBoost lowers the standard deviation of the scores (but the average score does not improve).

See the console's output for further details about each model.

In this example you might try to:

1. vary the `max_depth` for the `DecisionTreeClassifier` and `AdaBoostClassifier`, perhaps try `max_depth=3` for the `DecisionTreeClassifier` or `max_depth=None` for `AdaBoostClassifier`
2. vary `n_estimators`

It is worth noting that RandomForests and ExtraTrees can be fitted in parallel on many cores as each tree is built independently of the others. AdaBoost's samples are built sequentially and so do not use multiple cores.

Out:

```
DecisionTree with features [0, 1] has a score of 0.926666666667
RandomForest with 30 estimators with features [0, 1] has a score of 0.926666666667
ExtraTrees with 30 estimators with features [0, 1] has a score of 0.926666666667
AdaBoost with 30 estimators with features [0, 1] has a score of 0.84
DecisionTree with features [0, 2] has a score of 0.993333333333
RandomForest with 30 estimators with features [0, 2] has a score of 0.993333333333
ExtraTrees with 30 estimators with features [0, 2] has a score of 0.993333333333
AdaBoost with 30 estimators with features [0, 2] has a score of 0.993333333333
DecisionTree with features [2, 3] has a score of 0.993333333333
RandomForest with 30 estimators with features [2, 3] has a score of 0.993333333333
ExtraTrees with 30 estimators with features [2, 3] has a score of 0.993333333333
AdaBoost with 30 estimators with features [2, 3] has a score of 0.993333333333

## 16.2 Comparison of F-test and mutual information

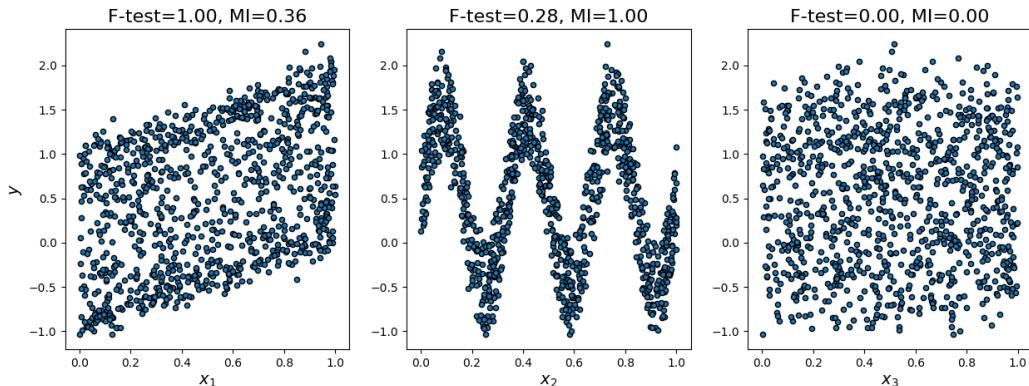

This example illustrates the differences between univariate F-test statistics and mutual information.

We consider 3 features  $x_1, x_2, x_3$  distributed uniformly over  $[0, 1]$ , the target depends on them as follows:

$y = x_1 + \sin(6 * \pi * x_2) + 0.1 * N(0, 1)$ , that is the third features is completely irrelevant.

The code below plots the dependency of  $y$  against individual  $x_i$  and normalized values of univariate F-tests statistics and mutual information.

As F-test captures only linear dependency, it rates  $x_1$  as the most discriminative feature. On the other hand, mutual information can capture any kind of dependency between variables and it rates  $x_2$  as the most discriminative feature, which probably agrees better with our intuitive perception for this example. Both methods correctly marks  $x_3$  as irrelevant.

```

print(__doc__)

import numpy as np
import matplotlib.pyplot as plt
from sklearn.feature_selection import f_regression, mutual_info_regression

np.random.seed(0)
X = np.random.rand(1000, 3)

## 16.6 Univariate Feature Selection

An example showing univariate feature selection.

Noisy (non informative) features are added to the iris data and univariate feature selection is applied. For each feature,

we plot the p-values for the univariate feature selection and the corresponding weights of an SVM. We can see that univariate feature selection selects the informative features and that these have larger SVM weights.

In the total set of features, only the 4 first ones are significant. We can see that they have the highest score with univariate feature selection. The SVM assigns a large weight to one of these features, but also Selects many of the non-informative features. Applying univariate feature selection before the SVM increases the SVM weight attributed to the significant features, and will thus improve classification.

```
print(__doc__)

import numpy as np
import matplotlib.pyplot as plt

from sklearn import datasets, svm
from sklearn.feature_selection import SelectPercentile, f_classif
```

import some data to play with

```
# The iris dataset
iris = datasets.load_iris()

# Some noisy data not correlated
E = np.random.uniform(0, 0.1, size=(len(iris.data), 20))

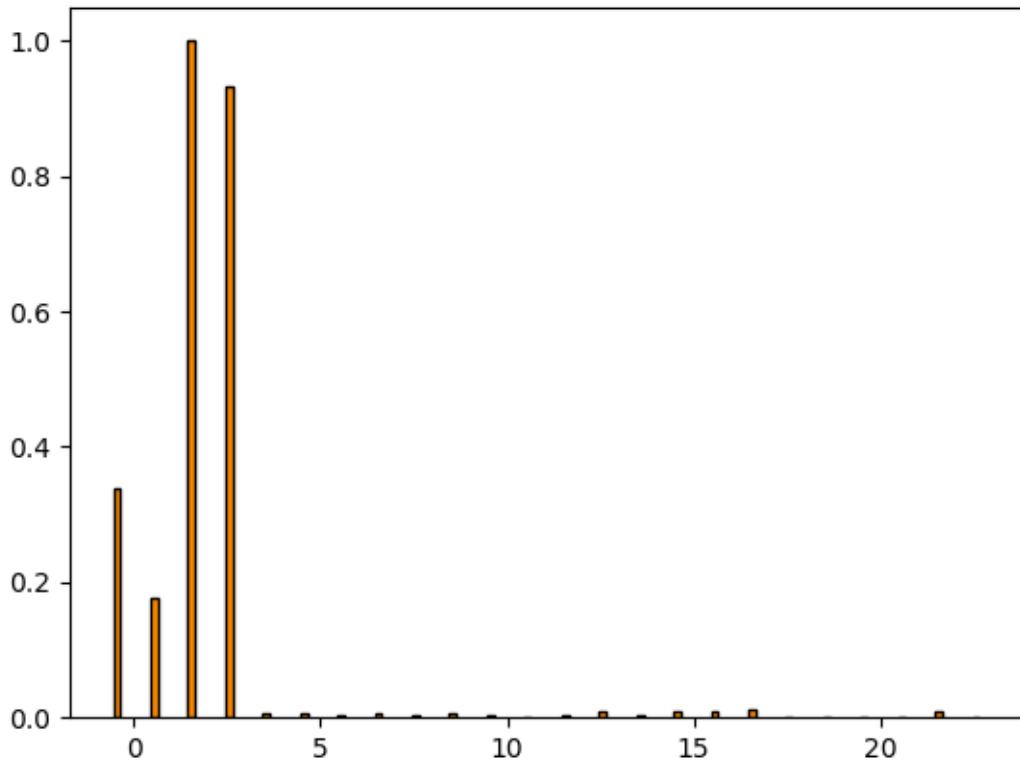

# Add the noisy data to the informative features
X = np.hstack((iris.data, E))
y = iris.target
```

```

## GAUSSIAN PROCESS FOR MACHINE LEARNING

Examples concerning the `sklearn.gaussian_process` module.

### 17.1 Illustration of Gaussian process classification (GPC) on the XOR dataset

This example illustrates GPC on XOR data. Compared are a stationary, isotropic kernel (RBF) and a non-stationary kernel (DotProduct). On this particular dataset, the DotProduct kernel obtains considerably better results because the class-boundaries are linear and coincide with the coordinate axes. In general, stationary kernels often obtain better results.

```

## 17.3 Comparison of kernel ridge and Gaussian process regression

Both kernel ridge regression (KRR) and Gaussian process regression (GPR) learn a target function by employing internally the “kernel trick”. KRR learns a linear function in the space induced by the respective kernel which corresponds to a non-linear function in the original space. The linear function in the kernel space is chosen based on the mean-squared error loss with ridge regularization. GPR uses the kernel to define the covariance of a prior distribution over the target functions and uses the observed training data to define a likelihood function. Based on Bayes theorem, a (Gaussian) posterior distribution over target functions is defined, whose mean is used for prediction.

A major difference is that GPR can choose the kernel’s hyperparameters based on gradient-ascent on the marginal likelihood function while KRR needs to perform a grid search on a cross-validated loss function (mean-squared error loss). A further difference is that GPR learns a generative, probabilistic model of the target function and can thus provide meaningful confidence intervals and posterior samples along with the predictions while KRR only provides predictions.

This example illustrates both methods on an artificial dataset, which consists of a sinusoidal target function and strong noise. The figure compares the learned model of KRR and GPR based on a ExpSineSquared kernel, which is suited for learning periodic functions. The kernel’s hyperparameters control the smoothness (l) and periodicity of the kernel (p). Moreover, the noise level of the data is learned explicitly by GPR by an additional WhiteKernel component in the kernel and by the regularization parameter alpha of KRR.

The figure shows that both methods learn reasonable models of the target function. GPR correctly identifies the periodicity of the function to be roughly  $2\pi$  (6.28), while KRR chooses the doubled periodicity  $4\pi$ . Besides that, GPR provides reasonable confidence bounds on the prediction which are not available for KRR. A major difference between the two methods is the time required for fitting and predicting: while fitting KRR is fast in principle, the grid-search for hyperparameter optimization scales exponentially with the number of hyperparameters (“curse of dimensionality”). The gradient-based optimization of the parameters in GPR does not suffer from this exponential scaling and is thus considerably faster on this example with 3-dimensional hyperparameter space. The time for predicting is similar; however, generating the variance of the predictive distribution of GPR takes considerable longer than just predicting the mean.

Out:

```
Time for KRR fitting: 8.329
Time for GPR fitting: 0.158
Time for KRR prediction: 0.083
Time for GPR prediction: 0.093
Time for GPR prediction with standard-deviation: 0.105
```

## 17.4 Gaussian process regression (GPR) on Mauna Loa CO2 data.

This example is based on Section 5.4.3 of “Gaussian Processes for Machine Learning” [RW2006]. It illustrates an example of complex kernel engineering and hyperparameter optimization using gradient ascent on the log-marginal-likelihood. The data consists of the monthly average atmospheric CO<sub>2</sub> concentrations (in parts per million by volume (ppmv)) collected at the Mauna Loa Observatory in Hawaii, between 1958 and 1997. The objective is to model the CO<sub>2</sub> concentration as a function of the time t.

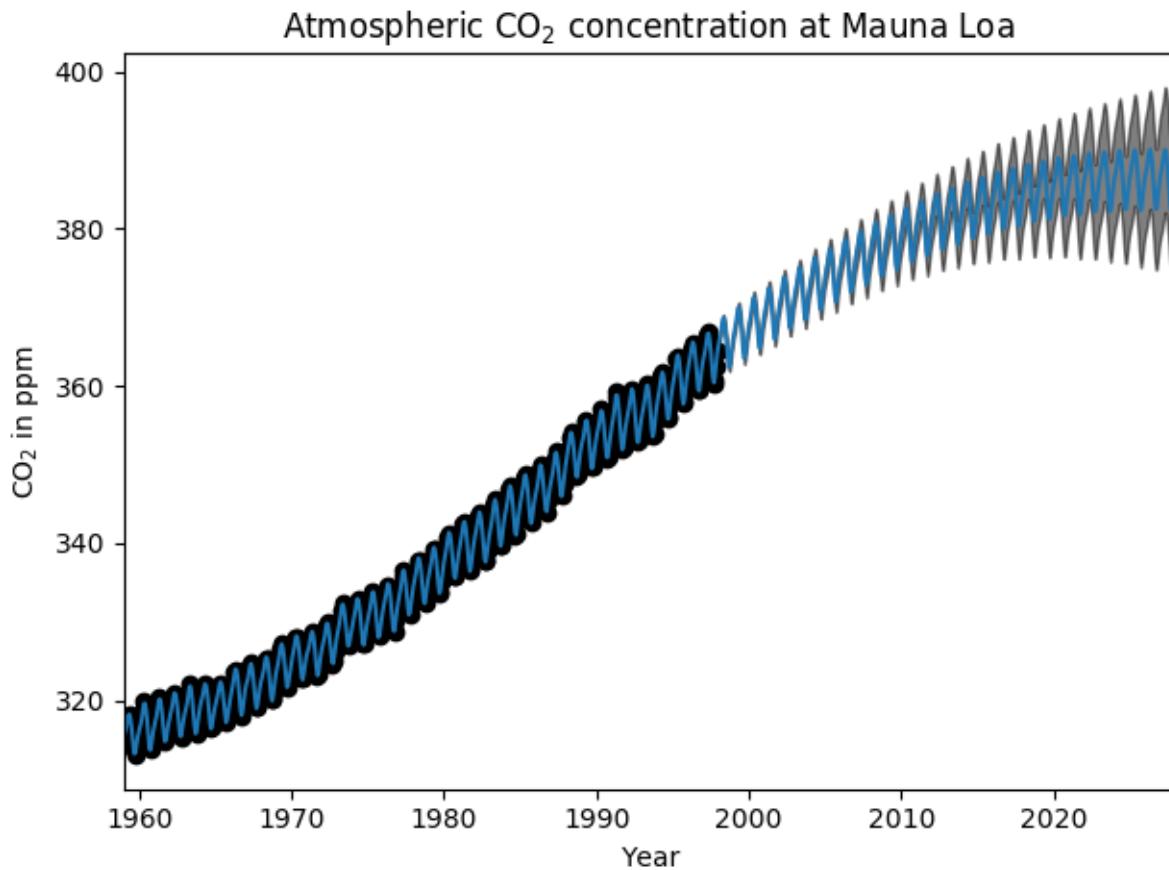

The kernel is composed of several terms that are responsible for explaining different properties of the signal:

- a long term, smooth rising trend is to be explained by an RBF kernel. The RBF kernel with a large length-scale enforces this component to be smooth; it is not enforced that the trend is rising which leaves this choice to the GP. The specific length-scale and the amplitude are free hyperparameters.
- a seasonal component, which is to be explained by the periodic ExpSineSquared kernel with a fixed periodicity of 1 year. The length-scale of this periodic component, controlling its smoothness, is a free parameter. In order to allow decaying away from exact periodicity, the product with an RBF kernel is taken. The length-scale of this RBF component controls the decay time and is a further free parameter.
- smaller, medium term irregularities are to be explained by a RationalQuadratic kernel component, whose length-scale and alpha parameter, which determines the diffuseness of the length-scales, are to be determined. According to [RW2006], these irregularities can better be explained by a RationalQuadratic than an RBF kernel component, probably because it can accommodate several length-scales.
- a “noise” term, consisting of an RBF kernel contribution, which shall explain the correlated noise components such as local weather phenomena, and a WhiteKernel contribution for the white noise. The relative amplitudes and the RBF’s length scale are further free parameters.

Maximizing the log-marginal-likelihood after subtracting the target’s mean yields the following kernel with an LML of -83.214:

```
34.4**2 * RBF(length_scale=41.8)
+ 3.27**2 * RBF(length_scale=180) * ExpSineSquared(length_scale=1.44,
                                                       periodicity=1)
+ 0.446**2 * RationalQuadratic(alpha=17.7, length_scale=0.957)
+ 0.197**2 * RBF(length_scale=0.138) + WhiteKernel(noise_level=0.0336)
```

Thus, most of the target signal (34.4ppm) is explained by a long-term rising trend (length-scale 41.8 years). The periodic component has an amplitude of 3.27ppm, a decay time of 180 years and a length-scale of 1.44. The long decay time indicates that we have a locally very close to periodic seasonal component. The correlated noise has an amplitude of 0.197ppm with a length scale of 0.138 years and a white-noise contribution of 0.197ppm. Thus, the overall noise level is very small, indicating that the data can be very well explained by the model. The figure shows also that the model makes very confident predictions until around 2015.

Out:

```
GPML kernel: 66**2 * RBF(length_scale=67) + 2.4**2 * RBF(length_scale=90) *
    ↪ ExpSineSquared(length_scale=1.3, periodicity=1) + 0.66**2 *
    ↪ RationalQuadratic(alpha=0.78, length_scale=1.2) + 0.18**2 * RBF(length_scale=0.134) *
    ↪+ WhiteKernel(noise_level=0.0361)

## 17.7 Probabilistic predictions with Gaussian process classification (GPC)

This example illustrates the predicted probability of GPC for an RBF kernel with different choices of the hyperparameters. The first figure shows the predicted probability of GPC with arbitrarily chosen hyperparameters and with the hyperparameters corresponding to the maximum log-marginal-likelihood (LML).

While the hyperparameters chosen by optimizing LML have a considerable larger LML, they perform slightly worse according to the log-loss on test data. The figure shows that this is because they exhibit a steep change of the class probabilities at the class boundaries (which is good) but have predicted probabilities close to 0.5 far away from the class boundaries (which is bad). This undesirable effect is caused by the Laplace approximation used internally by GPC.

The second figure shows the log-marginal-likelihood for different choices of the kernel's hyperparameters, highlighting

the two choices of the hyperparameters used in the first figure by black dots.

Out:

```
Log Marginal Likelihood (initial): -17.598
Log Marginal Likelihood (optimized): -3.875
Accuracy: 1.000 (initial) 1.000 (optimized)
Log-loss: 0.214 (initial) 0.319 (optimized)

## 17.8 Gaussian process regression (GPR) with noise-level estimation

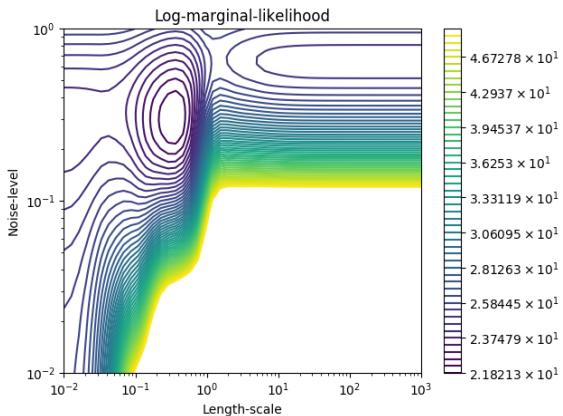

This example illustrates that GPR with a sum-kernel including a WhiteKernel can estimate the noise level of data. An illustration of the log-marginal-likelihood (LML) landscape shows that there exist two local maxima of LML. The first corresponds to a model with a high noise level and a large length scale, which explains all variations in the data by noise. The second one has a smaller noise level and shorter length scale, which explains most of the variation by the noise-free functional relationship. The second model has a higher likelihood; however, depending on the initial value for the hyperparameters, the gradient-based optimization might also converge to the high-noise solution. It is thus important to repeat the optimization several times for different initializations.

Initial:  $1^{**}2 * \text{RBF}(\text{length\_scale}=100) + \text{WhiteKernel}(\text{noise\_level}=1)$   
 optimum:  $0.00316^{**}2 * \text{RBF}(\text{length\_scale}=109) + \text{WhiteKernel}(\text{noise\_level}=0.6)$   
 Log-Marginal-Likelihood: -23.872337362

Initial:  $1^{**}2 * \text{RBF}(\text{length\_scale}=1) + \text{WhiteKernel}(\text{noise\_level}=1e-05)$   
 optimum:  $0.64^{**}2 * \text{RBF}(\text{length\_scale}=0.365) + \text{WhiteKernel}(\text{noise\_level}=0.29)$   
 Log-Marginal-Likelihood: -21.8050908902

## 17.9 Gaussian Processes regression: basic introductory example

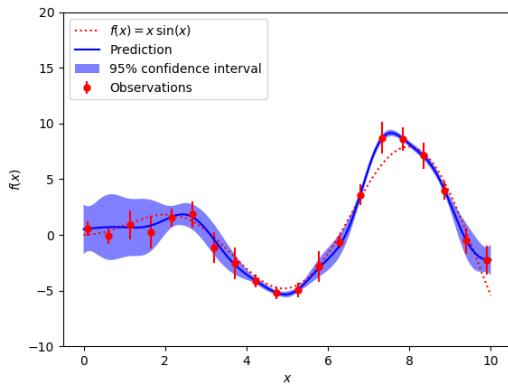

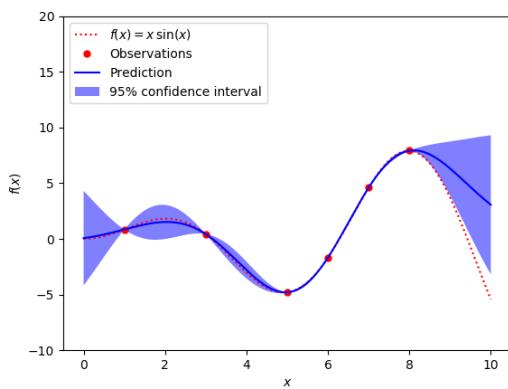

A simple one-dimensional regression example computed in two different ways:

1. A noise-free case
2. A noisy case with known noise-level per datapoint

In both cases, the kernel's parameters are estimated using the maximum likelihood principle.

The figures illustrate the interpolating property of the Gaussian Process model as well as its probabilistic nature in the form of a pointwise 95% confidence interval.

Note that the parameter `alpha` is applied as a Tikhonov regularization of the assumed covariance between the training points.

## 18.2 Plot Ridge coefficients as a function of the regularization

Shows the effect of collinearity in the coefficients of an estimator.

*Ridge* Regression is the estimator used in this example. Each color represents a different feature of the coefficient vector, and this is displayed as a function of the regularization parameter.

This example also shows the usefulness of applying Ridge regression to highly ill-conditioned matrices. For such matrices, a slight change in the target variable can cause huge variances in the calculated weights. In such cases, it is useful to set a certain regularization (alpha) to reduce this variation (noise).

When alpha is very large, the regularization effect dominates the squared loss function and the coefficients tend to zero. At the end of the path, as alpha tends toward zero and the solution tends towards the ordinary least squares, coefficients exhibit big oscillations. In practise it is necessary to tune alpha in such a way that a balance is maintained between both.

## 18.6 Plot Ridge coefficients as a function of the L2 regularization

*Ridge* Regression is the estimator used in this example. Each color in the left plot represents one different dimension of the coefficient vector, and this is displayed as a function of the regularization parameter. The right plot shows how exact the solution is. This example illustrates how a well defined solution is found by Ridge regression and how regularization affects the coefficients and their values. The plot on the right shows how the difference of the coefficients from the estimator changes as a function of regularization.

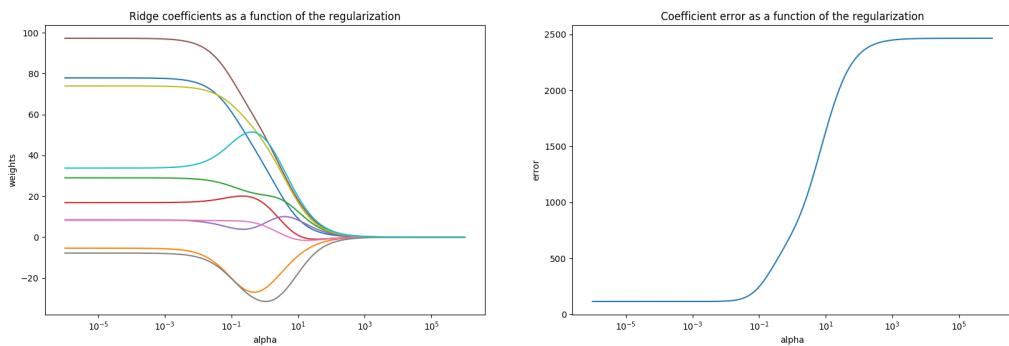

In this example the dependent variable Y is set as a function of the input features:  $y = X^*w + c$ . The coefficient vector w is randomly sampled from a normal distribution, whereas the bias term c is set to a constant.

As alpha tends toward zero the coefficients found by Ridge regression stabilize towards the randomly sampled vector w. For big alpha (strong regularisation) the coefficients are smaller (eventually converging at 0) leading to a simpler and biased solution. These dependencies can be observed on the left plot.

The right plot shows the mean squared error between the coefficients found by the model and the chosen vector w. Less regularised models retrieve the exact coefficients (error is equal to 0), stronger regularised models increase the

error.

Please note that in this example the data is non-noisy, hence it is possible to extract the exact coefficients.

## 18.7 Ordinary Least Squares and Ridge Regression Variance

Due to the few points in each dimension and the straight line that linear regression uses to follow these points as well as it can, noise on the observations will cause great variance as shown in the first plot. Every line's slope can vary quite a bit for each prediction due to the noise induced in the observations.

Ridge regression is basically minimizing a penalised version of the least-squared function. The penalising *shrinks* the value of the regression coefficients. Despite the few data points in each dimension, the slope of the prediction is much more stable and the variance in the line itself is greatly reduced, in comparison to that of the standard linear regression

## 18.9 Polynomial interpolation

This example demonstrates how to approximate a function with a polynomial of degree n\_degree by using ridge regression. Concretely, from n\_samples 1d points, it suffices to build the Vandermonde matrix, which is n\_samples x n\_degree+1 and has the following form:

`[[1, x_1, x_1 ** 2, x_1 ** 3, ...], [1, x_2, x_2 ** 2, x_2 ** 3, ...], ...]`

Intuitively, this matrix can be interpreted as a matrix of pseudo features (the points raised to some power). The matrix is akin to (but different from) the matrix induced by a polynomial kernel.

This example shows that you can do non-linear regression with a linear model, using a pipeline to add non-linear features. Kernel methods extend this idea and can induce very high (even infinite) dimensional feature spaces.

```

## 18.12 Linear Regression Example

This example uses the only the first feature of the *diabetes* dataset, in order to illustrate a two-dimensional plot of this regression technique. The straight line can be seen in the plot, showing how linear regression attempts to draw a straight line that will best minimize the residual sum of squares between the observed responses in the dataset, and the responses predicted by the linear approximation.

The coefficients, the residual sum of squares and the variance score are also calculated.

Out:

```
Coefficients:  
[ 938.23786125]  
Mean squared error: 2548.07  
Variance score: 0.47
```

```
print(__doc__)

## 18.17 Joint feature selection with multi-task Lasso

The multi-task lasso allows to fit multiple regression problems jointly enforcing the selected features to be the same across tasks. This example simulates sequential measurements, each task is a time instant, and the relevant features vary in amplitude over time while being the same. The multi-task lasso imposes that features that are selected at one time point are select for all time point. This makes feature selection by the Lasso more stable.

## 18.19 HuberRegressor vs Ridge on dataset with strong outliers

Fit Ridge and HuberRegressor on a dataset with outliers.

The example shows that the predictions in ridge are strongly influenced by the outliers present in the dataset. The Huber regressor is less influenced by the outliers since the model uses the linear loss for these. As the parameter epsilon is increased for the Huber regressor, the decision function approaches that of the ridge.

```

## 18.21 MNIST classification using multinomial logistic + L1

Here we fit a multinomial logistic regression with L1 penalty on a subset of the MNIST digits classification task. We use the SAGA algorithm for this purpose: this a solver that is fast when the number of samples is significantly larger than the number of features and is able to finely optimize non-smooth objective functions which is the case with the l1-penalty. Test accuracy reaches > 0.8, while weight vectors remains *sparse* and therefore more easily *interpretable*.

Note that this accuracy of this l1-penalized linear model is significantly below what can be reached by an l2-penalized linear model or a non-linear multi-layer perceptron model on this dataset.

Classification vector for...

Out:

```
Sparsity with L1 penalty: 82.72%
Test score with L1 penalty: 0.8320
Example run in 4.321 s
```

```

## 18.24 Theil-Sen Regression

Computes a Theil-Sen Regression on a synthetic dataset.

See [Theil-Sen estimator: generalized-median-based estimator](#) for more information on the regressor.

Compared to the OLS (ordinary least squares) estimator, the Theil-Sen estimator is robust against outliers. It has a breakdown point of about 29.3% in case of a simple linear regression which means that it can tolerate arbitrary corrupted data (outliers) of up to 29.3% in the two-dimensional case.

The estimation of the model is done by calculating the slopes and intercepts of a subpopulation of all possible combinations of p subsample points. If an intercept is fitted, p must be greater than or equal to n\_features + 1. The final slope and intercept is then defined as the spatial median of these slopes and intercepts.

In certain cases Theil-Sen performs better than [RANSAC](#) which is also a robust method. This is illustrated in the second example below where outliers with respect to the x-axis perturb RANSAC. Tuning the residual\_threshold parameter of RANSAC remedies this but in general a priori knowledge about the data and the nature of the outliers is needed. Due to the computational complexity of Theil-Sen it is recommended to use it only for small problems in terms of number of samples and features. For larger problems the max\_subpopulation parameter restricts the magnitude of all possible combinations of p subsample points to a randomly chosen subset and therefore also limits the runtime. Therefore, Theil-Sen is applicable to larger problems with the drawback of losing some of its mathematical properties since it then works on a random subset.

## 18.25 L1 Penalty and Sparsity in Logistic Regression

Comparison of the sparsity (percentage of zero coefficients) of solutions when L1 and L2 penalty are used for different values of C. We can see that large values of C give more freedom to the model. Conversely, smaller values of C

constrain the model more. In the L1 penalty case, this leads to sparser solutions.

We classify 8x8 images of digits into two classes: 0-4 against 5-9. The visualization shows coefficients of the models for varying C.

Out:

```
C=100.00
Sparsity with L1 penalty: 6.25%
score with L1 penalty: 0.9104
Sparsity with L2 penalty: 4.69%
score with L2 penalty: 0.9098
C=1.00
Sparsity with L1 penalty: 10.94%
score with L1 penalty: 0.9104
Sparsity with L2 penalty: 4.69%
score with L2 penalty: 0.9093
C=0.01
Sparsity with L1 penalty: 85.94%
score with L1 penalty: 0.8614
Sparsity with L2 penalty: 4.69%
score with L2 penalty: 0.8915
```

```

## 18.27 Robust linear estimator fitting

Here a sine function is fit with a polynomial of order 3, for values close to zero.

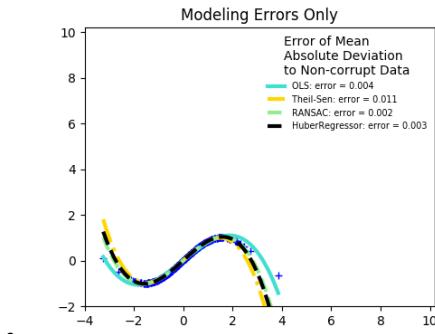

Robust fitting is demoed in different situations:

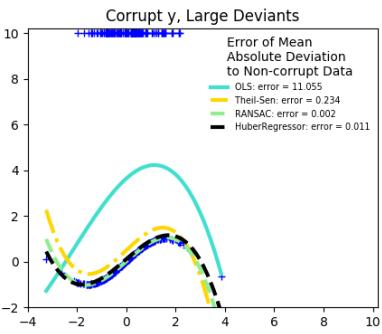

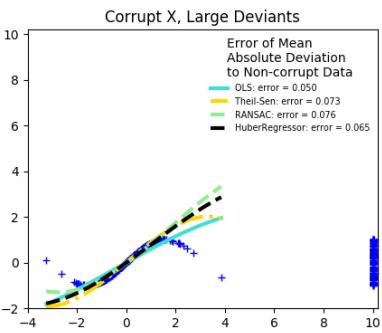

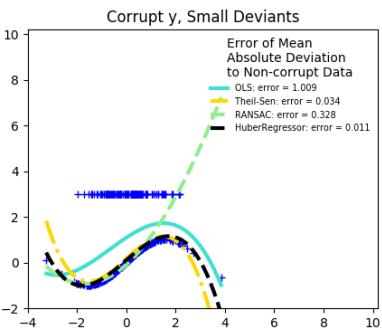

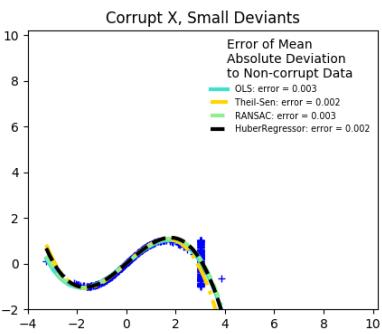

- No measurement errors, only modelling errors (fitting a sine with a polynomial)
- Measurement errors in X
- Measurement errors in y

The median absolute deviation to non corrupt new data is used to judge the quality of the prediction.

What we can see that:

- RANSAC is good for strong outliers in the y direction
- TheilSen is good for small outliers, both in direction X and y, but has a break point above which it performs worse than OLS.
- The scores of HuberRegressor may not be compared directly to both TheilSen and RANSAC because it does not attempt to completely filter the outliers but lessen their effect.

```
from matplotlib import pyplot as plt

Computes a Bayesian Ridge Regression on a synthetic dataset.

See [Bayesian Ridge Regression](#) for more information on the regressor.

Compared to the OLS (ordinary least squares) estimator, the coefficient weights are slightly shifted toward zeros, which stabilises them.

As the prior on the weights is a Gaussian prior, the histogram of the estimated weights is Gaussian.

The estimation of the model is done by iteratively maximizing the marginal log-likelihood of the observations.

We also plot predictions and uncertainties for Bayesian Ridge Regression for one dimensional regression using polynomial feature expansion. Note the uncertainty starts going up on the right side of the plot. This is because these test samples are outside of the range of the training samples.

```

## 18.31 Lasso model selection: Cross-Validation / AIC / BIC

Use the Akaike information criterion (AIC), the Bayes Information criterion (BIC) and cross-validation to select an optimal value of the regularization parameter alpha of the *Lasso* estimator.

Results obtained with LassoLarsIC are based on AIC/BIC criteria.

Information-criterion based model selection is very fast, but it relies on a proper estimation of degrees of freedom, are derived for large samples (asymptotic results) and assume the model is correct, i.e. that the data are actually generated by this model. They also tend to break when the problem is badly conditioned (more features than samples).

For cross-validation, we use 20-fold with 2 algorithms to compute the Lasso path: coordinate descent, as implemented by the LassoCV class, and Lars (least angle regression) as implemented by the LassoLarsCV class. Both algorithms give roughly the same results. They differ with regards to their execution speed and sources of numerical errors.

Lars computes a path solution only for each kink in the path. As a result, it is very efficient when there are only few kinks, which is the case if there are few features or samples. Also, it is able to compute the full path without setting any meta parameter. On the opposite, coordinate descent compute the path points on a pre-specified grid (here we use the default). Thus it is more efficient if the number of grid points is smaller than the number of kinks in the path. Such a strategy can be interesting if the number of features is really large and there are enough samples to select a large amount. In terms of numerical errors, for heavily correlated variables, Lars will accumulate more errors, while the coordinate descent algorithm will only sample the path on a grid.

Note how the optimal value of alpha varies for each fold. This illustrates why nested-cross validation is necessary when trying to evaluate the performance of a method for which a parameter is chosen by cross-validation: this choice of parameter may not be optimal for unseen data.

## 18.32 Multiclass sparse logistic regression on newsgroups20

Comparison of multinomial logistic L1 vs one-versus-rest L1 logistic regression to classify documents from the newsgroups20 dataset. Multinomial logistic regression yields more accurate results and is faster to train on the larger scale dataset.

Here we use the  $\ell_1$  sparsity that trims the weights of not informative features to zero. This is good if the goal is to extract the strongly discriminative vocabulary of each class. If the goal is to get the best predictive accuracy, it is better to use the non sparsity-inducing  $\ell_2$  penalty instead.

A more traditional (and possibly better) way to predict on a sparse subset of input features would be to use univariate feature selection followed by a traditional ( $\ell_2$ -penalised) logistic regression model.

### Multinomial vs One-vs-Rest Logistic L1 Dataset 20newsgroups

## 18.33 Sparse recovery: feature selection for sparse linear models

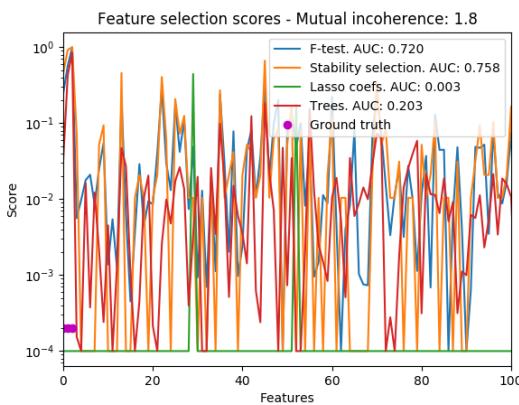

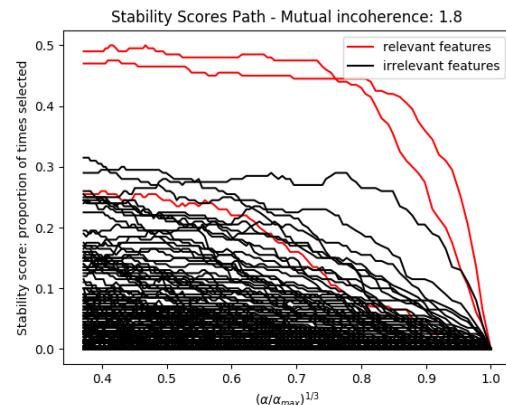

Given a small number of observations, we want to recover which features of  $X$  are relevant to explain  $y$ . For this *sparse linear models* can outperform standard statistical tests if the true model is sparse, i.e. if a small fraction of the features are relevant.

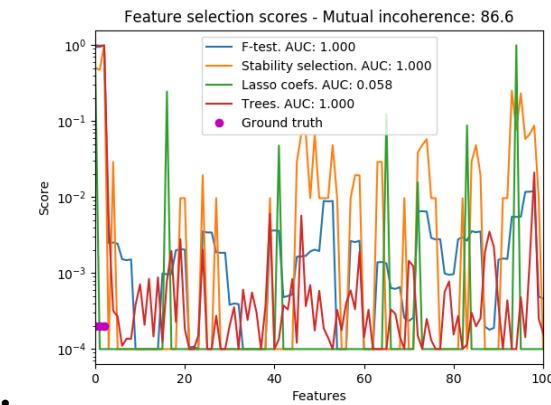

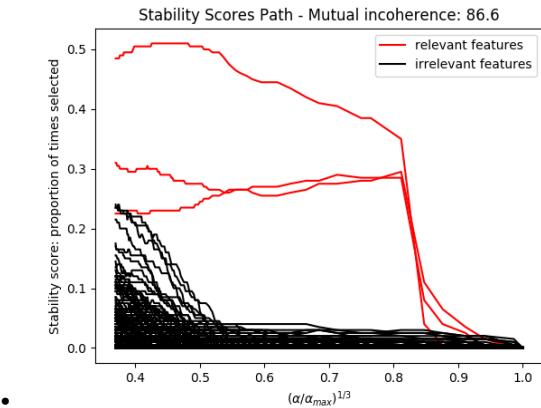

As detailed in [the compressive sensing notes](#), the ability of L1-based approach to identify the relevant variables depends on the sparsity of the ground truth, the number of samples, the number of features, the conditioning of the design matrix on the signal subspace, the amount of noise, and the absolute value of the smallest non-zero coefficient [Wainwright2006] (<http://statistics.berkeley.edu/sites/default/files/tech-reports/709.pdf>).

Here we keep all parameters constant and vary the conditioning of the design matrix. For a well-conditioned design matrix (small mutual incoherence) we are exactly in compressive sensing conditions (i.i.d Gaussian sensing matrix), and L1-recovery with the Lasso performs very well. For an ill-conditioned matrix (high mutual incoherence), regressors are very correlated, and the Lasso randomly selects one. However, randomized-Lasso can recover the ground truth well.

In each situation, we first vary the alpha parameter setting the sparsity of the estimated model and look at the stability scores of the randomized Lasso. This analysis, knowing the ground truth, shows an optimal regime in which relevant features stand out from the irrelevant ones. If alpha is chosen too small, non-relevant variables enter the model. On the opposite, if alpha is selected too large, the Lasso is equivalent to stepwise regression, and thus brings no advantage over a univariate F-test.

In a second time, we set alpha and compare the performance of different feature selection methods, using the area under curve (AUC) of the precision-recall.

## 19.4 Manifold Learning methods on a severed sphere

An application of the different *Manifold learning* techniques on a spherical data-set. Here one can see the use of dimensionality reduction in order to gain some intuition regarding the manifold learning methods. Regarding the dataset, the poles are cut from the sphere, as well as a thin slice down its side. This enables the manifold learning techniques to ‘spread it open’ whilst projecting it onto two dimensions.

For a similar example, where the methods are applied to the S-curve dataset, see [Comparison of Manifold Learning methods](#)

Note that the purpose of the *MDS* is to find a low-dimensional representation of the data (here 2D) in which the distances respect well the distances in the original high-dimensional space, unlike other manifold-learning algorithms, it does not seek an isotropic representation of the data in the low-dimensional space. Here the manifold problem matches fairly that of representing a flat map of the Earth, as with map projection

## 19.5 Manifold learning on handwritten digits: Locally Linear Embedding, Isomap...

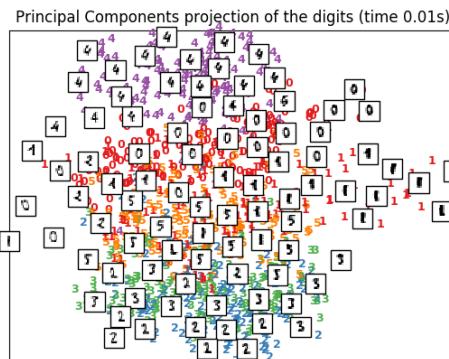

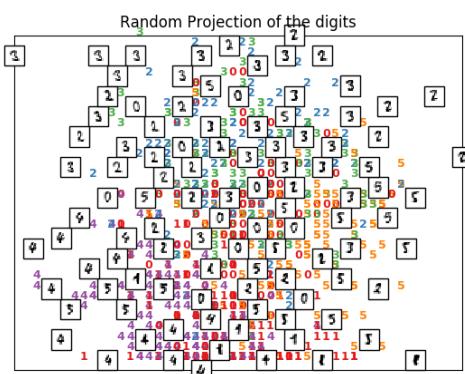

An illustration of various embeddings on the digits dataset.

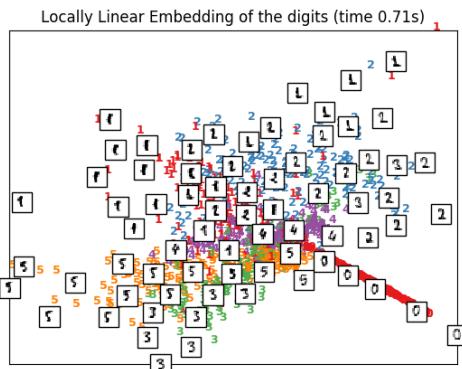

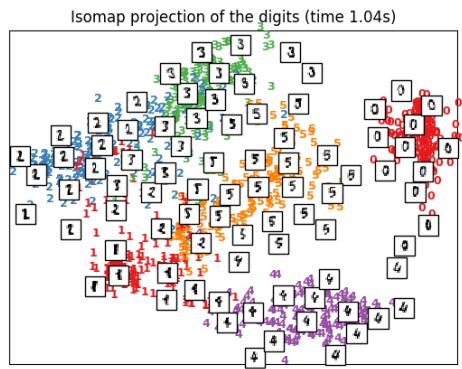

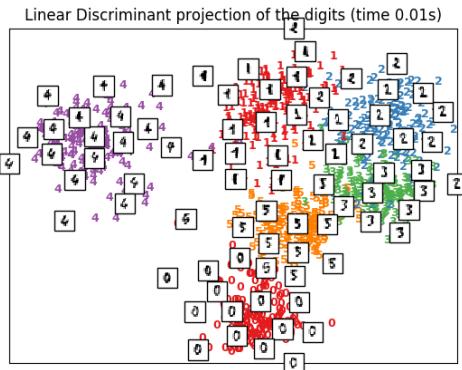

The RandomTreesEmbedding, from the `sklearn.ensemble` module, is not technically a manifold embedding method, as it learn a high-dimensional representation on which we apply a dimensionality reduction method. However, it is often useful to cast a dataset into a representation in which the classes are linearly-separable.

t-SNE will be initialized with the embedding that is generated by PCA in this example, which is not the default setting. It ensures global stability of the embedding, i.e., the embedding does not depend on random initialization.

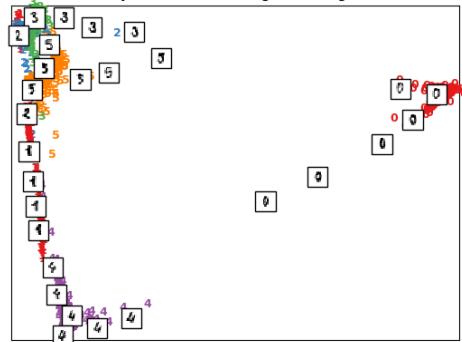

A selection from the 64-dimensional digits dataset

## GAUSSIAN MIXTURE MODELS

Examples concerning the `sklearn.mixture` module.

### 20.1 Density Estimation for a Gaussian mixture

Plot the density estimation of a mixture of two Gaussians. Data is generated from two Gaussians with different centers and covariance matrices.

```
import numpy as np
import matplotlib.pyplot as plt
from matplotlib.colors import LogNorm
```

```

from sklearn import mixture

n_samples = 300

# generate random sample, two components
np.random.seed(0)

# generate spherical data centered on (20, 20)
shifted_gaussian = np.random.randn(n_samples, 2) + np.array([20, 20])

# generate zero centered stretched Gaussian data
C = np.array([[0., -0.7], [3.5, .7]])
stretched_gaussian = np.dot(np.random.randn(n_samples, 2), C)

# concatenate the two datasets into the final training set
X_train = np.vstack([shifted_gaussian, stretched_gaussian])

# fit a Gaussian Mixture Model with two components
clf = mixture.GaussianMixture(n_components=2, covariance_type='full')
clf.fit(X_train)

# display predicted scores by the model as a contour plot
x = np.linspace(-20., 30.)
y = np.linspace(-20., 40.)
X, Y = np.meshgrid(x, y)
XX = np.array([X.ravel(), Y.ravel()]).T
Z = -clf.score_samples(XX)
Z = Z.reshape(X.shape)

CS = plt.contour(X, Y, Z, norm=LogNorm(vmin=1.0, vmax=1000.0),
                 levels=np.logspace(0, 3, 10))
CB = plt.colorbar(CS, shrink=0.8, extend='both')
plt.scatter(X_train[:, 0], X_train[:, 1], .8)

plt.title('Negative log-likelihood predicted by a GMM')
plt.axis('tight')
plt.show()

## 20.2 Gaussian Mixture Model Ellipsoids

Plot the confidence ellipsoids of a mixture of two Gaussians obtained with Expectation Maximisation (GaussianMixture class) and Variational Inference (BayesianGaussianMixture class models with a Dirichlet process prior).

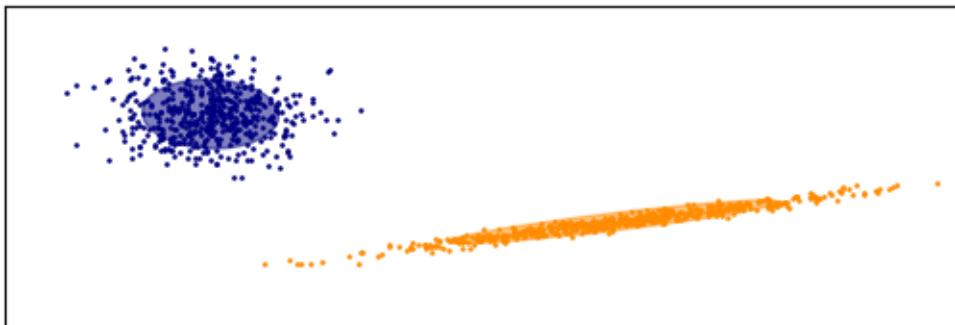

Both models have access to five components with which to fit the data. Note that the Expectation Maximisation model will necessarily use all five components while the Variational Inference model will effectively only use as many as are needed for a good fit. Here we can see that the Expectation Maximisation model splits some components arbitrarily, because it is trying to fit too many components, while the Dirichlet Process model adapts its number of states automatically.

This example doesn't show it, as we're in a low-dimensional space, but another advantage of the Dirichlet process model is that it can fit full covariance matrices effectively even when there are less examples per cluster than there are dimensions in the data, due to regularization properties of the inference algorithm.

## 20.3 Gaussian Mixture Model Selection

This example shows that model selection can be performed with Gaussian Mixture Models using information-theoretic criteria (BIC). Model selection concerns both the covariance type and the number of components in the model. In that case, AIC also provides the right result (not shown to save time), but BIC is better suited if the problem is to identify the right model. Unlike Bayesian procedures, such inferences are prior-free.

In that case, the model with 2 components and full covariance (which corresponds to the true generative model) is selected.

```

import numpy as np
import itertools

from scipy import linalg
import matplotlib.pyplot as plt
import matplotlib as mpl

from sklearn import mixture

## 20.4 GMM covariances

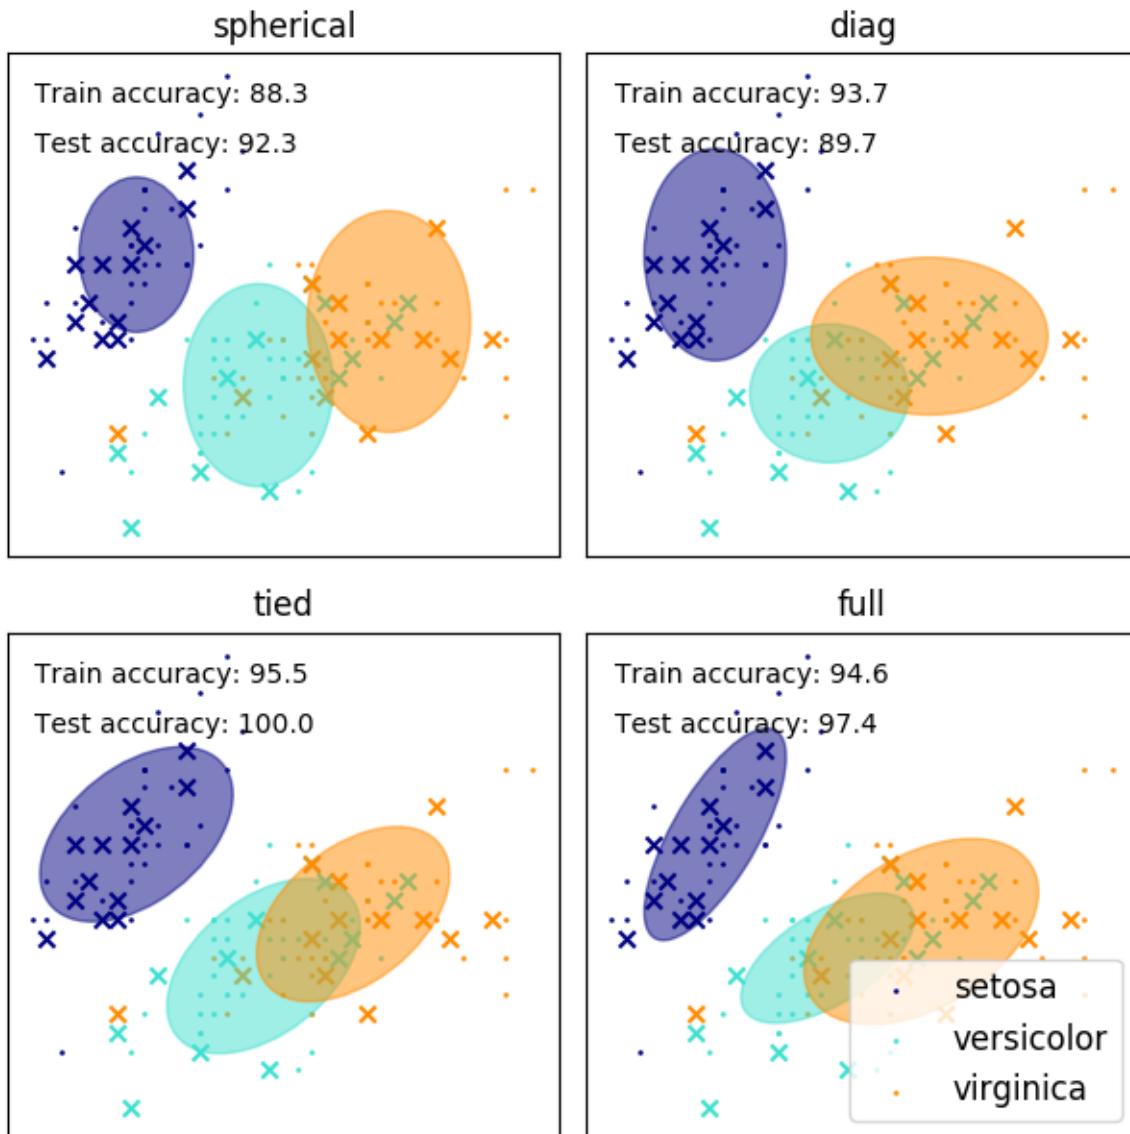

Demonstration of several covariances types for Gaussian mixture models.

See [Gaussian mixture models](#) for more information on the estimator.

Although GMM are often used for clustering, we can compare the obtained clusters with the actual classes from the dataset. We initialize the means of the Gaussians with the means of the classes from the training set to make this comparison valid.

We plot predicted labels on both training and held out test data using a variety of GMM covariance types on the iris dataset. We compare GMMs with spherical, diagonal, full, and tied covariance matrices in increasing order of performance. Although one would expect full covariance to perform best in general, it is prone to overfitting on small datasets and does not generalize well to held out test data.

On the plots, train data is shown as dots, while test data is shown as crosses. The iris dataset is four-dimensional. Only the first two dimensions are shown here, and thus some points are separated in other dimensions.

## 20.5 Gaussian Mixture Model Sine Curve

This example demonstrates the behavior of Gaussian mixture models fit on data that was not sampled from a mixture of Gaussian random variables. The dataset is formed by 100 points loosely spaced following a noisy sine curve. There is therefore no ground truth value for the number of Gaussian components.

The first model is a classical Gaussian Mixture Model with 10 components fit with the Expectation-Maximization algorithm.

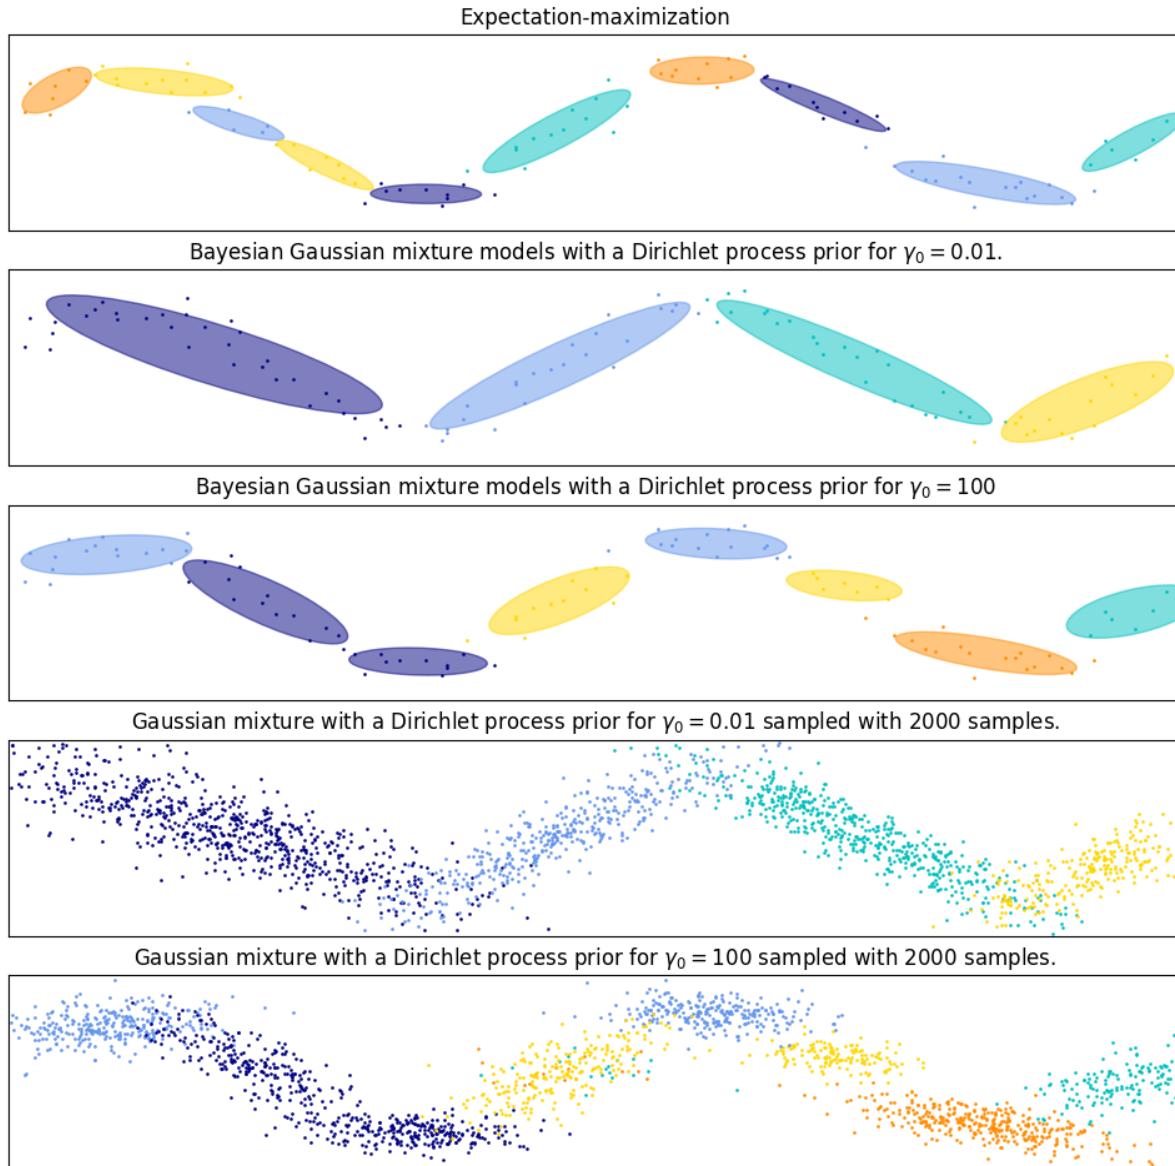

The second model is a Bayesian Gaussian Mixture Model with a Dirichlet process prior fit with variational inference. The low value of the concentration prior makes the model favor a lower number of active components. This models “decides” to focus its modeling power on the big picture of the structure of the dataset: groups of points with alternating directions modeled by non-diagonal covariance matrices. Those alternating directions roughly capture the alternating nature of the original sine signal.

The third model is also a Bayesian Gaussian mixture model with a Dirichlet process prior but this time the value of the concentration prior is higher giving the model more liberty to model the fine-grained structure of the data. The result

is a mixture with a larger number of active components that is similar to the first model where we arbitrarily decided to fix the number of components to 10.

Which model is the best is a matter of subjective judgement: do we want to favor models that only capture the big picture to summarize and explain most of the structure of the data while ignoring the details or do we prefer models that closely follow the high density regions of the signal?

The last two panels show how we can sample from the last two models. The resulting samples distributions do not look exactly like the original data distribution. The difference primarily stems from the approximation error we made by using a model that assumes that the data was generated by a finite number of Gaussian components instead of a continuous noisy sine curve.

## 20.6 Concentration Prior Type Analysis of Variation Bayesian Gaussian Mixture

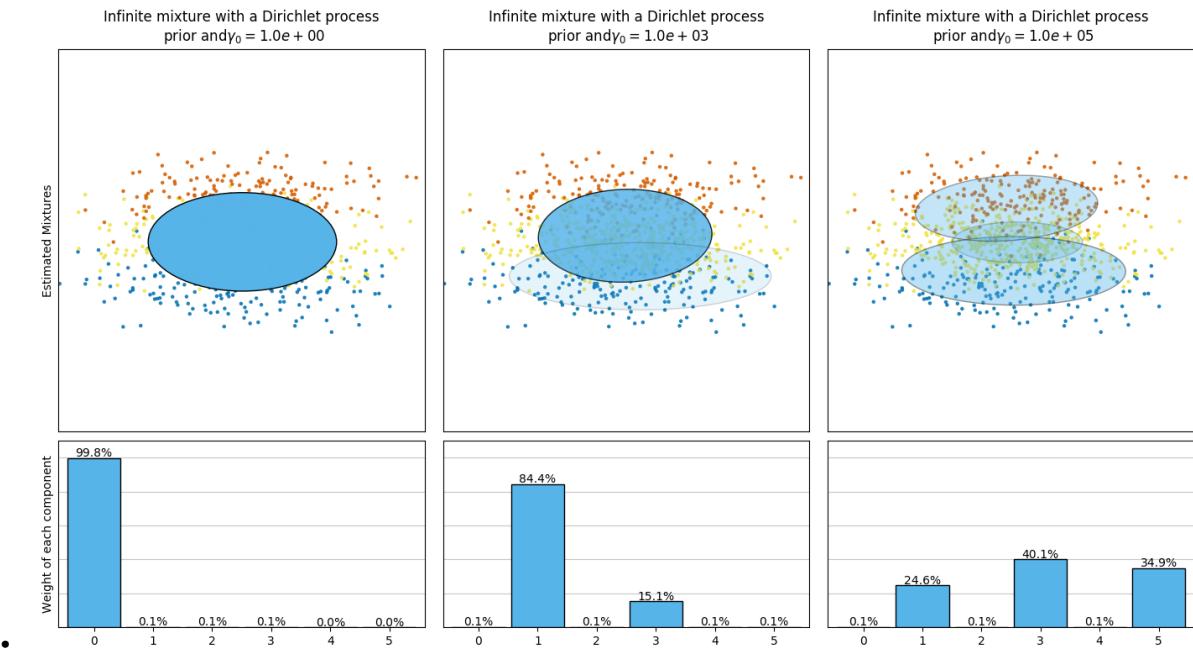

This example plots the ellipsoids obtained from a toy dataset (mixture of three Gaussians) fitted by the `BayesianGaussianMixture` class models with a Dirichlet distribution prior (`weight_concentration_prior_type='dirichlet_distribution'`) and a Dirichlet process prior (`weight_concentration_prior_type='dirichlet_process'`). On each figure, we plot the results for three different values of the weight concentration prior.

The `BayesianGaussianMixture` class can adapt its number of mixture components automatically. The parameter `weight_concentration_prior` has a direct link with the resulting number of components with non-zero weights. Specifying a low value for the concentration prior will make the model put most of the weight on few components set the remaining components weights very close to zero. High values of the concentration prior will allow a larger number of components to be active in the mixture.

The Dirichlet process prior allows to define an infinite number of components and automatically selects the correct number of components: it activates a component only if it is necessary.

On the contrary the classical finite mixture model with a Dirichlet distribution prior will favor more uniformly weighted components and therefore tends to divide natural clusters into unnecessary sub-components.

## MODEL SELECTION

Examples related to the `sklearn.model_selection` module.

### 21.1 Plotting Validation Curves

In this plot you can see the training scores and validation scores of an SVM for different values of the kernel parameter gamma. For very low values of gamma, you can see that both the training score and the validation score are low. This is called underfitting. Medium values of gamma will result in high values for both scores, i.e. the classifier is performing fairly well. If gamma is too high, the classifier will overfit, which means that the training score is good but the validation score is poor.

```

print(__doc__)

## 21.2 Underfitting vs. Overfitting

This example demonstrates the problems of underfitting and overfitting and how we can use linear regression with polynomial features to approximate nonlinear functions. The plot shows the function that we want to approximate, which is a part of the cosine function. In addition, the samples from the real function and the approximations of different models are displayed. The models have polynomial features of different degrees. We can see that a linear function (polynomial with degree 1) is not sufficient to fit the training samples. This is called **underfitting**. A polynomial of degree 4 approximates the true function almost perfectly. However, for higher degrees the model will **overfit** the training data, i.e. it learns the noise of the training data. We evaluate quantitatively **overfitting** /

**underfitting** by using cross-validation. We calculate the mean squared error (MSE) on the validation set, the higher, the less likely the model generalizes correctly from the training data.

```

## 21.3 Train error vs Test error

Illustration of how the performance of an estimator on unseen data (test data) is not the same as the performance on training data. As the regularization increases the performance on train decreases while the performance on test is optimal within a range of values of the regularization parameter. The example with an Elastic-Net regression model and the performance is measured using the explained variance a.k.a. R<sup>2</sup>.

## 21.4 Receiver Operating Characteristic (ROC) with cross validation

Example of Receiver Operating Characteristic (ROC) metric to evaluate classifier output quality using cross-validation.

ROC curves typically feature true positive rate on the Y axis, and false positive rate on the X axis. This means that the top left corner of the plot is the “ideal” point - a false positive rate of zero, and a true positive rate of one. This is not very realistic, but it does mean that a larger area under the curve (AUC) is usually better.

The “steepness” of ROC curves is also important, since it is ideal to maximize the true positive rate while minimizing the false positive rate.

This example shows the ROC response of different datasets, created from K-fold cross-validation. Taking all of these curves, it is possible to calculate the mean area under curve, and see the variance of the curve when the training set is split into different subsets. This roughly shows how the classifier output is affected by changes in the training data, and how different the splits generated by K-fold cross-validation are from one another.

---

## 21.5 Parameter estimation using grid search with cross-validation

This examples shows how a classifier is optimized by cross-validation, which is done using the `sklearn.model_selection.GridSearchCV` object on a development set that comprises only half of the available labeled data.

The performance of the selected hyper-parameters and trained model is then measured on a dedicated evaluation set that was not used during the model selection step.

More details on tools available for model selection can be found in the sections on *Cross-validation: evaluating estimator performance* and *Tuning the hyper-parameters of an estimator*.

Out:

```
# Tuning hyper-parameters for precision

Best parameters set found on development set:

{'C': 10, 'gamma': 0.001, 'kernel': 'rbf'}

Grid scores on development set:

0.986 (+/-0.016) for {'C': 1, 'gamma': 0.001, 'kernel': 'rbf'}
0.959 (+/-0.029) for {'C': 1, 'gamma': 0.0001, 'kernel': 'rbf'}
0.988 (+/-0.017) for {'C': 10, 'gamma': 0.001, 'kernel': 'rbf'}
0.982 (+/-0.026) for {'C': 10, 'gamma': 0.0001, 'kernel': 'rbf'}
0.988 (+/-0.017) for {'C': 100, 'gamma': 0.001, 'kernel': 'rbf'}
0.982 (+/-0.025) for {'C': 100, 'gamma': 0.0001, 'kernel': 'rbf'}
0.988 (+/-0.017) for {'C': 1000, 'gamma': 0.001, 'kernel': 'rbf'}

## 21.6 Confusion matrix

Example of confusion matrix usage to evaluate the quality of the output of a classifier on the iris data set. The diagonal elements represent the number of points for which the predicted label is equal to the true label, while off-diagonal elements are those that are mislabeled by the classifier. The higher the diagonal values of the confusion matrix the better, indicating many correct predictions.

The figures show the confusion matrix with and without normalization by class support size (number of elements in each class). This kind of normalization can be interesting in case of class imbalance to have a more visual interpretation of which class is being misclassified.

Here the results are not as good as they could be as our choice for the regularization parameter C was not the best. In real life applications this parameter is usually chosen using [Tuning the hyper-parameters of an estimator](#).

Out:

```
Confusion matrix, without normalization
[[13  0  0]
 [ 0 10  6]
 [ 0  0  9]]
Normalized confusion matrix

## 21.7 Comparing randomized search and grid search for hyperparameter estimation

Compare randomized search and grid search for optimizing hyperparameters of a random forest. All parameters that influence the learning are searched simultaneously (except for the number of estimators, which poses a time / quality tradeoff).

The randomized search and the grid search explore exactly the same space of parameters. The result in parameter settings is quite similar, while the run time for randomized search is drastically lower.

The performance is slightly worse for the randomized search, though this is most likely a noise effect and would not carry over to a held-out test set.

Note that in practice, one would not search over this many different parameters simultaneously using grid search, but pick only the ones deemed most important.

Out:

```
RandomizedSearchCV took 4.62 seconds for 20 candidates parameter settings.

## 21.8 Nested versus non-nested cross-validation

This example compares non-nested and nested cross-validation strategies on a classifier of the iris data set. Nested cross-validation (CV) is often used to train a model in which hyperparameters also need to be optimized. Nested CV estimates the generalization error of the underlying model and its (hyper)parameter search. Choosing the parameters that maximize non-nested CV biases the model to the dataset, yielding an overly-optimistic score.

Model selection without nested CV uses the same data to tune model parameters and evaluate model performance. Information may thus “leak” into the model and overfit the data. The magnitude of this effect is primarily dependent on the size of the dataset and the stability of the model. See Cawley and Talbot<sup>1</sup> for an analysis of these issues.

To avoid this problem, nested CV effectively uses a series of train/validation/test set splits. In the inner loop (here executed by `GridSearchCV`), the score is approximately maximized by fitting a model to each training

<sup>1</sup> Cawley, G.C.; Talbot, N.L.C. On over-fitting in model selection and subsequent selection bias in performance evaluation. *J. Mach. Learn. Res.* 2010, 11, 2079-2107.

set, and then directly maximized in selecting (hyper)parameters over the validation set. In the outer loop (here in `cross_val_score`), generalization error is estimated by averaging test set scores over several dataset splits.

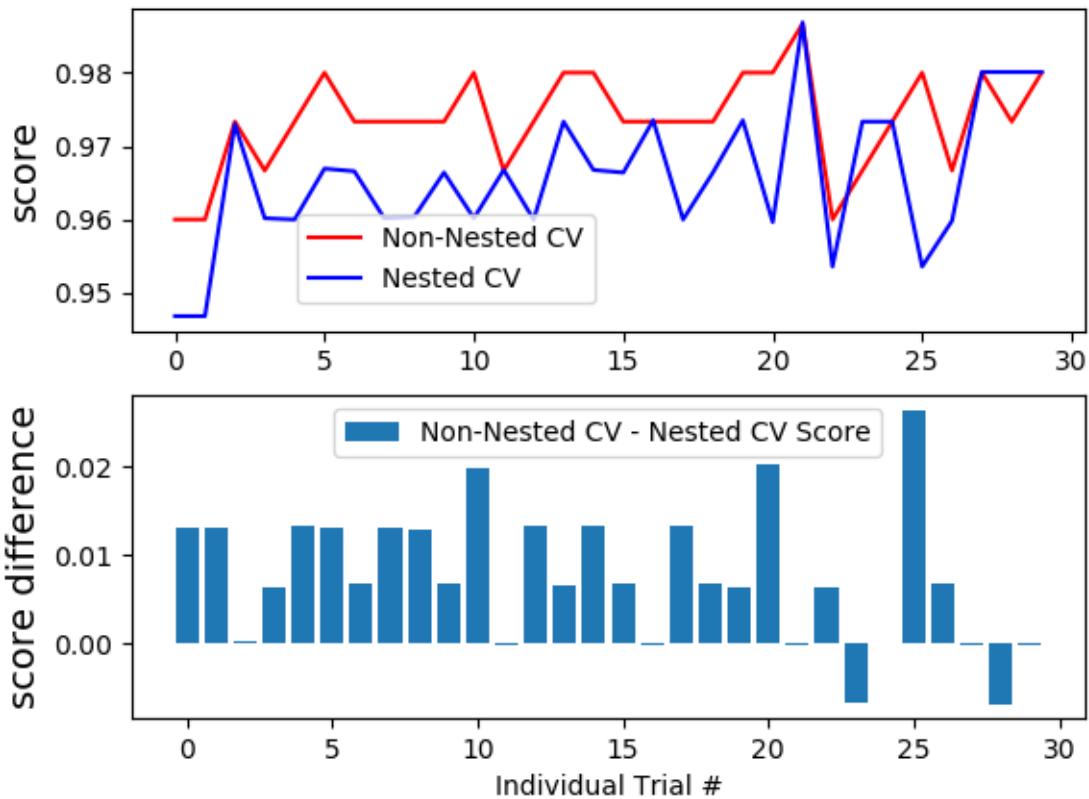

The example below uses a support vector classifier with a non-linear kernel to build a model with optimized hyperparameters by grid search. We compare the performance of non-nested and nested CV strategies by taking the difference between their scores.

## 21.9 Sample pipeline for text feature extraction and evaluation

The dataset used in this example is the 20 newsgroups dataset which will be automatically downloaded and then cached and reused for the document classification example.

You can adjust the number of categories by giving their names to the dataset loader or setting them to None to get the 20 of them.

Here is a sample output of a run on a quad-core machine:

```

Loading 20 newsgroups dataset for categories:
['alt.atheism', 'talk.religion.misc']
1427 documents
2 categories

Performing grid search...
pipeline: ['vect', 'tfidf', 'clf']
parameters:
{'clf__alpha': (1.000000000000001e-05, 9.99999999999995e-07),
 'clf__n_iter': (10, 50, 80),
 'clf__penalty': ('l2', 'elasticnet'),
 'tfidf__use_idf': (True, False),
 'vect__max_n': (1, 2),
 'vect__max_df': (0.5, 0.75, 1.0),
 'vect__max_features': (None, 5000, 10000, 50000)}
done in 1737.030s

Best score: 0.940
Best parameters set:
  clf__alpha: 9.99999999999995e-07
  clf__n_iter: 50
  clf__penalty: 'elasticnet'
  tfidf__use_idf: True
  vect__max_n: 2

```

```
vect_max_df: 0.75
vect_max_features: 50000
```

```

## 21.10 Receiver Operating Characteristic (ROC)

Example of Receiver Operating Characteristic (ROC) metric to evaluate classifier output quality.

ROC curves typically feature true positive rate on the Y axis, and false positive rate on the X axis. This means that the top left corner of the plot is the “ideal” point - a false positive rate of zero, and a true positive rate of one. This is not very realistic, but it does mean that a larger area under the curve (AUC) is usually better.

The “steepness” of ROC curves is also important, since it is ideal to maximize the true positive rate while minimizing the false positive rate.

### 21.10.1 Multiclass settings

ROC curves are typically used in binary classification to study the output of a classifier. In order to extend ROC curve and ROC area to multi-class or multi-label classification, it is necessary to binarize the output. One ROC curve can be drawn per label, but one can also draw a ROC curve by considering each element of the label indicator matrix as a binary prediction (micro-averaging).

Another evaluation measure for multi-class classification is macro-averaging, which gives equal weight to the classification of each label.

---

**Note:**

See also `sklearn.metrics.roc_auc_score`, *Receiver Operating Characteristic (ROC) with cross validation*.
